During most of the 1980's, the phycobiliproteins were very much in the limelight, which was appropriate not only because lime is about the right excitation wavelength, but because they provided a means of attaching several efficient fluorescent labels, with spectra in regions in which cellular autofluorescence is minimal, to antibodies and other ligands. The fuss about the phycobiliproteins diverted many people's attention from the search for other, low molecular weight fluorescent labels with large Stokes' shifts and/or with excitation maxima in the green, red, and infrared spectral regions. In terms of the design of lower molecular weight labels, one of more successful efforts has been the development of **reactive cyanine dye labels**, largely due to the persistence of Alan Waggoner and his colleagues<sup>1361-4</sup>.

Cyanines, like many of the compounds now in use as laser dyes, are not soluble to any appreciable extent in water, but are soluble in nonpolar solvents. This characteristic is essential to the use of cyanine dyes as probes of membrane potential, as it allows the dyes to pass freely through the lipid bilayer portion of cytoplasmic and organellar membranes, but is undesirable in labels because it increases the tendency of unconjugated label to stick to protein and the tendency of conjugates to bind nonspecifically by this mechanism. There is, in fact, considerable interest in the preparation of water-soluble analogues of existing laser dyes for use as laser dyes, since the substitution of aqueous dye solutions for the solutions in organic solvents now employed would make it easier to keep the dye medium cool.

The spectral characteristics of most fluorescent organic dyes are determined by the structure of the heterocyclic ring(s), and the conjugated double bonds connecting rings, if such connections are present (they are in cyanines), which form the backbone of the dye. Water solubility and reactivity can be modified by the addition of functional groups on the ring; many of the functional groups that can be added to increase water solubility may also be capable of being derivatized to produce dye molecules that can be covalently bound to proteins, etc. The art lies in adding the functional groups in ways that do not substantially alter spectra.

The first attempts of which I am aware to produce reactive derivatives of cyanines (A. Waggoner & H. Shapiro, unpublished), around 1981, failed to yield suitable antibody labels; the compounds synthesized shifted their absorption maxima and decreased their quantum efficiency on conjugation. Waggoner's group subsequently produced cyanines that could bind covalently to protein sulfhydryl groups<sup>1361</sup>, and then isothiocyanate derivatives<sup>1362</sup>. The two newest series

of labels<sup>1363-4</sup> use a succinimidyl ester group to link to proteins; the first of these<sup>1363</sup> employed carboxymethyl groups to increase solubility, while the second<sup>1364</sup> uses sulfonate substituents for the purpose.

The reactive **oxacarbo-cyanine** dye **Cy2** (see Figure 7-9) shares the spectrum of the DiOC<sub>N</sub>(3) series of dyes, which are well known as membrane potential probes. The absorption and emission spectral characteristics of these dyes are similar to those of fluorescein.

**Cy3** and **Cy5** are, respectively, derived from **indocarbo-cyanine** and **indodicarbo-cyanine**; their spectral characteristics are shown in Figure 7-9. **Cy3** absorbs maximally at about 545 nm, and can be excited most effectively with a green He-Ne laser source at 543 nm or the mercury arc lamp line at 546 nm; however, the absorption of the material is high enough that it excites adequately at the 488 nm argon laser wavelength available in most cytometers. The 515 nm argon laser line is better, as are krypton lines at 520 and 530 nm and the emission from a frequency-doubled YAG laser at 532 nm. The emission peak of **Cy3** is at about 565 nm; however, a substantial fraction of **Cy3** emission is transmitted by the bandpass filters typically used for phycoerythrin detection. **Cy5** absorbs maximally near 640 nm; used by itself, it is very effectively excited by 633 nm He-Ne lasers, 635-650 nm diode lasers, or the 647 nm krypton laser line. For immunofluorescence work, **Cy5** is now probably more widely used in the form of **PE-Cy5 tandem conjugates**<sup>359</sup>, which can be excited at 488 nm, than as a primary label.

**Cy5.5** is a reactive derivative of **dibenzoindodicarbo-cyanine**, with maximal absorption near 675 nm and maximal emission at 695-700 nm. This material is optimally excited by 670 nm diode lasers, which are dirt cheap (think red laser pointers); its absorption at 633 nm is sufficient to make it possible to use **Cy5**- and **Cy5.5**-labeled antibodies for two-color immunofluorescence analyses in an instrument with a 633 nm He-Ne or 635-650 nm diode laser source. The **IMAGN 2000**, a clinical instrument which did lymphocyte subset analysis by a low-resolution scanning technique dubbed **volumetric capillary cytometry**<sup>1365,2484,2641</sup>, rather than flow cytometry, used **Cy5** and **Cy5.5** as antibody labels. **Biometric Imaging**, which produced the instrument, was acquired by Becton-Dickinson. **Cy3.5**, with maximum absorption near 580 nm and maximum emission near 600 nm, is to **Cy3** as **Cy5.5** is to **Cy5**.

Wessendorf and Brelje<sup>1366</sup>, using microscopy and densitometry rather than flow cytometry, compared the brightness of immunofluorescent staining with the same antibody tagged with fluorescein, tetramethylrhodamine, Lissamine rhodamine, Texas Red, and **Cy3.18**, an early cyanine label; they concluded that the cyanine dye was brightest. This is not too surprising; cyanine dyes have higher extinction coefficients than most other dyes, and quantum efficiencies at least as high, and these authors used excitation wavelengths optimal for the individual dyes.

**Cy7** is a reactive indotricarbo-cyanine dye; it absorbs in the near infrared (about 750 nm) and emits around 770 nm.

The indotricarbocyanine structure itself is not as stable chemically as are the indodicarbocyanine and -carbocyanine dyes fluorophores of Cy5 and Cy3; this makes it harder to prepare Cy7 labels and also results in a relatively short shelf life. Like Cy5, Cy7 is more widely used as an acceptor in PE- and APC-based tandems than as a primary immunofluorescent label; while Cy2, Cy3, and Cy5 are fairly popular as labels for nucleic acid probes used in **fluorescence in situ hybridization (FISH)**, Cy7 seems not to be.

Cy3, Cy5, and related dyes are available from **Amer-sham Biosciences** in kits that contain just about everything needed for antibody conjugation except the antibody.

There is a “sticking point” to cyanine dye labels; antibodies labeled with Cy3, Cy5, and/or PE-Cy5 and, possibly, other cyanines, seem to adhere to monocytes and, to a lesser extent, to granulocytes, resulting in low levels of nonspecific staining. I first heard about this from Carl Stewart and from Alan Waggoner, and the three of us (unpublished) demonstrated the effect using Cy3 and Cy5 antibodies in a Cytomutt with 543 and 633 nm He-Ne laser excitation. The effect came to general attention when PE-Cy5 tandem conjugate-labeled antibodies came into wider use and were found to bind to monocytes even when the antibody was not reactive with monocyte surface antigens. According to van Vugt et al<sup>2642</sup>, this interaction involves the high-affinity IgG receptor CD64 present on the surface of monocytes. However, Stewart and Stewart<sup>2643</sup> report that some CD64-negative monocytic and myeloid leukemia cells also bind PE-Cy5 antibodies not reactive with their cell surface antigens. Tjioe et al<sup>2628</sup> noted that antibodies labeled with a PE-APC tandem conjugate bind to monocytes and granulocytes, although not to the same extent as do PE-Cy5-labeled antibodies. Antibody manufacturers have come up with various proprietary ways of minimizing such irrelevant binding.

### Blue Notes: AMCA and Cascade Blue

A number of **UV-excited, blue fluorescent labels** have come into use for antibody labeling. After having been told at least twice that fluorescein was adopted as a label because the UV-excited blue autofluorescence present in most cells and tissues interfered with the UV-excited blue fluorescence of anthracene, which was the first label, you might well ask why. The simple answer is that people who had “maxed out” their instruments in terms of the number of detectors they could have looking at the 488 nm beam and the krypton, dye, or He-Ne laser beam wanted to measure still more antigens. If you had a UV laser available, you could use a UV-excited, blue fluorescent label; if you restricted its use to antibodies for which the cells of interest have relatively large numbers of binding sites, you wouldn't have a big problem with autofluorescence.

The **coumarins** are a family of compounds that exhibit UV-excited blue fluorescence and that, incidentally, were originally used therapeutically as anticoagulants and, in proportionally larger doses, as rodent poisons. Coumarin derivatives have been exploited as laser dyes, and may also act as

pH indicators; the latter characteristic is usually an undesirable one for a label. The first popular coumarin label was **7-amino-4-methylcoumarin-3-acetic acid**, or **AMCA**. As shown in Figure 7-9, AMCA absorbs maximally at about 350 nm, and has an emission maximum near 455 nm; it can be excited optimally by argon or krypton UV lasers and by the mercury arc lamp line at 366 nm, and adequately by the 325 nm He-Cd laser line.

Aubry et al<sup>1367</sup> stated that, in addition to being usable for multicolor immunofluorescence analysis, AMCA was well suited for use in combination with acridine orange for simultaneous measurement of DNA and RNA content and cellular antigens, using UV and 488 nm excitation beams. My personal preference would be to use Hoechst 33342, pyronin Y, and fluorescein-antibodies<sup>113</sup> for the same purpose, in most cases; however, there are situations in which acridine orange may be more appropriate than pyronin for RNA content measurement, and also situations in which one would want to use acridine orange to measure something other than RNA content, e.g., DNA sensitivity to denaturation. In either of these cases, AMCA-labeled antibodies might be useful, provided the antigenic determinant of interest was preserved during the acridine orange staining procedure. Delia et al<sup>1368</sup> used AMCA as a third label in a flow cytometer with collinear UV and 488 nm illuminating beams. Molecular Probes' **Alexa 350**, a sulfonated amino-coumarin, has similar spectral characteristics, but a quantum yield almost twice as high as that of AMCA<sup>2348</sup>.

**Cascade Blue**<sup>1075,2332,2644</sup>, a reactive derivative of **pyrene**, was introduced by Molecular Probes; its spectrum is shown in Figure 7-9. The absorption maximum is near 390 nm. While absorption at 325 nm is probably too low to rely on a UV He-Cd laser for excitation, adequate excitation should be available from the 366 nm arc lamp line or the UV lines from argon or krypton or mode-locked tripled YAG lasers. Anderson et al<sup>2644</sup> excited both Cascade Blue and Molecular Probes' **Cascade Yellow** (emission maximum near 550 nm) using the violet krypton lines at 407 and 413 nm, and a violet diode laser should be usable as well. The emission maximum of Cascade Blue is at about 415 nm; emission above 500 nm is considerably less than is the case with AMCA and Alexa 350, facilitating compensation in multi-color immunofluorescence experiments.

### Hey, BODIPY!

Molecular Probes also offers the **BODIPY** dyes<sup>1675,2332</sup>; which are **boron dipyrromethane** derivatives with long enough formula names to justify one of the manufacturer's many catchy abbreviations. The original member of the series, **BODIPY FL**, has spectral properties similar to those of fluorescein, with a somewhat narrower emission peak, less sensitivity to pH changes, and greater resistance to bleaching, all desirable characteristics. The excitation maxima of the various BODIPY dyes cover the range from 500 to 646 nm; emission maxima range from 506 to 660 nm. Five of the most popular BODIPY dyes are available with water-

solubilizing spacers and amine-reactive ester groups attached to facilitate conjugation to antibodies or other proteins.

A variety of peptides, proteins, polysaccharides and other molecules with BODIPY dyes attached are also produced. **Bis-BODIPY-phosphatidylcholine**, localized in the inner leaflet of the plasma membrane, was used by Meshulam et al.<sup>60</sup> to measure phospholipase A activation in neutrophils by flow cytometry. Knaus et al.<sup>170,1</sup> and Martin et al.<sup>132</sup> have used BODIPY labeling with other small ligands; most recently, Haugland et al.<sup>133</sup> used phalloidin labeled with the new long-wavelength fluorophore **BODIPY 581/591** (581 nm excitation, 591 nm emission), which is spectrally similar to Texas Red, for fluorescence microscopic visualization of the intracellular distribution of F-actin. However, BODIPY dyes have still not moved as far up in the charts as might have been expected.

### Alexa Dyes: Some Thoughts on Dyemographics

I write a new edition of *Practical Flow Cytometry* every few years and, if I'm lucky, sell a few thousand copies. Dick Haugland, who founded Molecular Probes, puts together a new edition of his *Handbook*<sup>2332</sup> every few years, with updates at intervals on CDs and or his web site, and gives away tens of thousands of copies. The rest of the time, he presides over a large and talented group of people who make dyes. They might be considered dye hackers, in the old, honorable sense of the word; they know the structures and the spectra, and how to tweak the structures to optimize the performance of the dyes. And the company isn't losing money.

The **Alexa dyes**<sup>2352,2348</sup> are a series of sulfonated coumarin- and rhodamine-based labels, with spectral characteristics similar to those of some of the more popular labels previously mentioned in this section: e.g., AMCA, fluorescein, Texas red, Cy3, Cy5, Cy5.5, and Cy7. However, the Alexa dyes have higher quantum yields, better photostability, and better charge characteristics (allowing more dye molecules to be put on a protein before the law of diminishing returns cuts in on fluorescence). So what happens? People who do their own dye conjugations have written testimonials for the Alexa dyes in the latest edition of the *Handbook*<sup>2332</sup>, but the companies that make and sell antibodies in volume kept making conjugates with fluorescein, and tandems with Cy5, Cy5.5, and Cy7. The word on the street was that the antibody companies didn't want to pay the premium royalties Molecular Probes wanted to get paid for its premium dyes.

Just look at fluorescein, which is the Microsoft software equivalent in fluorescent labels. It has a lot of problems, e.g., its fluorescence yield varies markedly over the near-physiologic pH range, but, while everybody knows about, and many people complain about, the problems, the antibody manufacturers load fluorescein onto their antibodies, and almost everybody buys them and uses them. Molecular Probes has produced at least three green dyes – BODIPY FL, Oregon Green, and Alexa 488 – that are better labels than fluorescein, in most respects, including photostability,

which keeps the dyes green longer – with fluorescein envy. The race is not always to the swift.

Luckily, Molecular Probes does well enough to keep the Alexa dyes and a few thousand other gourmet chemicals in the catalogue for its discerning customers. And, as of early 2003, at least a few antibody producers (BD/Pharmingen and Caltag, for sure) had started to offer Alexa dye labels.

### Other Organic Fluorescent Labels: A Dye Named JOE, etc.

The DNA sequencing crowd uses fluorescent dyes, many of which are similar or identical to dyes used in cytometry, but is likely to know them by different names or nicknames. In the interest of nickname translation, I will mention that 6-JOE is 6-carboxy-4',5'-dichloro-2',7'-dimethoxyfluorescein, 5-FAM is 5-carboxyfluorescein, TAMRA is carboxytetramethylrhodamine, ROX is carboxy-X-rhodamine, and TET is c-carboxy-2',4,7,7'-tetrachlorofluorescein. The halogenated fluoresceins have excitation and emission maxima at somewhat longer wavelengths than those of fluorescein itself. Molecular Probes sells them in reactive form as succinimidyl esters for sequencing and probe labeling; there doesn't seem to be any compelling reason to use them in cytometry.

In the golden oldies department, I should mention **nitrobenzoxadiazole (NBD)** as a label; this material is usually applied to proteins in the form of its reactive chloride derivative, 4-chloro-7-nitrobenz-2-oxa-1,3-diazole (NBD chloride), which reacts with amino and thiol groups. The adduct with amino groups has spectral properties similar to fluorescein; Wallace et al.<sup>622</sup> used **NBD-phalloidin** for flow cytometric studies of cytoskeletal structure. NBD fluorescence is strongly environmentally dependent; for details, see the Molecular Probes *Handbook*<sup>2332</sup>.

Most dyes suitable for use in CW tunable dye lasers emitting in the red and infrared have absorption maxima in the orange and red spectral regions; reactive derivatives of these dyes should, in principle, be suitable labels for use in instruments with He-Ne or diode laser excitation in the red. Joel Wright and I (unpublished) fooled around with a derivative of the oxazine dye **Nile blue** without much luck in the early 1980's; Monsigny et al.<sup>174</sup> have, more recently, had better luck, producing both a **reactive benzoxazinone dye** with red emission that can be excited at 488 nm and another that apparently stains nucleic acids.

**Aluminum phthalocyanine dyes** have been derivatized for use as labels<sup>1375</sup>; these dyes themselves have been used as sensitizers for photodynamic treatment of cancer, and their uptake has been monitored by flow cytometry<sup>1376,8</sup>. The derivatized versions had strong absorption in the UV and red spectral regions with emission at longer red wavelengths. I was able (D. Schindele and H. Shapiro, unpublished) to resolve populations of beads labeled with two different aluminum phthalocyanine dyes in a cytometer with 670 nm diode laser illumination; I didn't have great luck with cells bearing antibodies labeled with phthalocyanine derivatives,

but further work along this line would seem worthwhile, if a source of the dyes can be found.

Whitaker et al.<sup>1379</sup> report that fluorescent **rhodol** derivatives can be made with fluorescence properties similar to fluorescein and rhodamine, but with better photostability and without the pH sensitivity of fluorescein.

In the development of laser dyes, attempts have been made to find and exploit chemical structures with fluorescence spectra showing large Stokes' shifts. Power levels of hundreds of milliwatts or more are required to pump CW dye lasers; at present, most dyes that emit in the red and infrared require a krypton ion laser (647/676 nm) for pumping. Since argon lasers are more tractable than their krypton counterparts, it would be desirable to use argon lasers as dye laser pumps for red- and IR-emitting dyes. Argon lasers, however, emit in the blue and green. Red and IR emission can be obtained with argon laser pumping when dyes with large Stokes' shifts, e.g., pyridyl and styryl dyes<sup>307-9</sup>, are used as the lasing media. Derivatives of these dyes might make good labels; the pyridyl and styryl dyes might also be useful in low molecular weight tandem labels.

The IR diode lasers used in CD players emit at around 785 nm, which is above the emission maximum of the longest-wavelength label discussed up to this point (Cy7). Since relatively high power (tens of milliwatts) 785 nm diode lasers cost only a few dollars, the notion of using such a laser to excite at least one additional fluorescent label is attractive. One principal problem with this approach is that dyes with the large conjugated ring structures needed to produce IR absorption tend to be chemically unstable. Linda Lee, who synthesized thiazole orange while at B-D<sup>769</sup>, made two relatively stable IR-excited dyes, **BHMP** and **BHDMAP**, during a brief stint at Biometric Imaging<sup>2645</sup>. The dyes, with emission maxima near 805 nm, were used successfully in a prototype volumetric capillary cytometer with dual (633 nm He-Ne and 785 nm diode) lasers. **BHMP** and **BHDMAP** are heptamethine cyanine dyes with a dialkylpyridinium ion at the central methine, which contributes to stability and makes the dyes water-soluble.

### Quantum Dots

A fair amount of buzz has recently been devoted to the prospect of using **semiconductor nanocrystals**, better known as **quantum dots**, as labels for biological molecules or as tags for beads used in multiplex assays<sup>2646-53</sup>.

In semiconductor light-emitting diodes (LEDs) and lasers, absorption of optical or electrical energy creates **electron-hole pairs**; one atom of the material temporarily loses an electron, while another somewhere in the vicinity temporarily gains one. When electron-hole pairs recombine, some of the absorbed energy is lost in the form of a photon. The emission wavelength is dependent on the **Bohr radius**, which is the average distance between electrons and holes in an excited-state pair. The Bohr radius is a function of the composition of the semiconductor material, but it normally on the order of tens of nanometers.

In semiconductor crystals with dimensions smaller than the Bohr radius, additional energy is required to create electron-hole pairs, and absorption and emission are thus shifted to shorter wavelengths. In such **nanocrystals**, typically no more than about 10 nm in diameter, the emission wavelength becomes more dependent on the size of the crystal than on its composition, since the energy required to keep an electron and a hole separated increases dramatically as the distance between them decreases. The emission wavelength of a CdSe crystal with a diameter of 2.1 nm is approximately 510 nm; that of a crystal with a 3.1 nm diameter crystal of the same material is approximately 560 nm.

The fluorescence spectrum of a nanocrystal is considerably different from that of an organic dye. Organic dyes (see Figure 4-7, p. 113, for the fluorescein spectrum) typically have small Stokes' shifts, i.e., their excitation maxima are within 20 nm of their emission maxima. The excitation spectrum and the emission spectrum of an organic dye often resemble mirror images of one another; both are substantially skewed, with a short-wavelength "shoulder" in the excitation spectrum and a long-wavelength "tail" in the emission spectrum.

The emission spectrum of a nanocrystal is typically symmetric, with a full width at half maximum of at most a few tens of nanometers, the emission bandwidth is thus substantially less than for a typical organic dye. This means that, given a pair of nanocrystals and a pair of dyes with the same emission peak wavelengths, a given combination of optical filters and dichroics will do a better job of separating fluorescence signals from the nanocrystals than of separating fluorescence signals from the dyes.

Moreover, the excitation spectra of nanocrystals are relatively independent of emission wavelength; progressively shorter wavelengths are increasingly effective for excitation. Excitation at 400 nm is typically at least twice that at 488 nm. This suggests that violet diode lasers will be economical and useful excitation sources for work with quantum dots, in either scanning or flow cytometers.

Being inorganic, nanocrystals are much less susceptible to photobleaching than are organic dyes; a nanocrystal is likely to be putting out over 75% of its original fluorescence output after an observation time sufficient to photobleach over 95% of the fluorescence emission from a dye. The relative chemical and photostabilities of nanocrystals should be particularly useful for work in the far red and infrared spectral regions (nanocrystals can be made with emission wavelengths above 1000 nm). Nanocrystals also have much higher absorption (and excitation) cross-sections than do dyes, meaning that, although the quantum efficiencies of nanocrystals and dyes are about the same, the fluorescence from a nanocrystal is typically equivalent to the fluorescence from a dozen or two dye molecules.

So why can't you buy 200 different monoclonal antibodies labeled with quantum dots? Well, as usual, there have been some practical problems, some of which appear to have been solved, and some of which remain.

Since both the emission wavelengths and the fluorescence intensities of nanocrystals depend on their size, preparative methods must yield crystals with highly homogenous size distributions in order to keep emission peaks confined to a small spectral range and maintain low emission bandwidths.

Earlier work with nanocrystals produced materials with fluorescence lifetimes in the range of 100 ns, which is definitely on the long side for flow cytometry, although acceptable for static cytometry and imaging. Newer materials have fluorescence lifetimes of approximately 15 ns, still a few times longer than the lifetimes of most commonly used dyes, but probably acceptable for flow cytometry.

Semiconductor materials don't much like hanging out in aqueous solutions. Practical quantum dot labels therefore must consist of a semiconductor core, a shell of another semiconductor material that confines excitation to the core, and an outer layer that allows the particle to remain dispersed in aqueous solution and that provides some means by which it may be attached to a biomolecule. CdSe crystals are typically made with ZnS or CdS shells; the hydrophilic coating may be silica or one of several sulfur-containing acids. A dihydrolipoic acid coating, in particular, readily binds avidin, allowing biotinylated antibodies to be bound to the coated crystals with very high affinity<sup>2654</sup>.

However, once you've made a particle the size of a quantum dot and coated it with something hydrophilic that binds proteins, you've increased the likelihood that the particle will be more or less nonspecifically bound to cells, and/or scarfed up by phagocytes. While the effects of phagocytosis on any particular experiment may be difficult to predict, nonspecific binding is almost certain to decrease the ratio of fluorescence intensities you measure from cells that do and do not bear the material you are trying to detect with the aid of a quantum dot label.

Preliminary results on flow and image cytometry of cells labeled with quantum dot-tagged antibodies were presented by Bill Hyun of UCSF and collaborators from **Quantum Dot Corporation** at the 2000 ISAC meeting<sup>2655</sup>, but I haven't yet seen a publication on flow cytometry using quantum dots. I guess people are still in the excited state over them, and need to relax and write a paper. You can now buy streptavidin-conjugated quantum dots with a 605 nm emission wavelength from Quantum Dot Corporation.

I put a brief writeup of green fluorescent protein in the last edition, guessing that while nobody had yet done flow cytometry of cells expressing GFP, it might be the next big thing; I have similar vibes about quantum dots. I won't tell you about all the predictions I made in earlier editions that didn't pan out, at least not here.

### Getting Labels Onto Molecules of Interest

If there is one basic principle applicable to labeling, whether the label is a large or a small molecule, fluorescent or nonfluorescent, and whether what is being labeled is an antibody, drug, hormone, or other material, it is this: It is

**absolutely critical to establish the effects of the fluorescent tagging procedure on the affinity and biological activity of the effector portion of the molecule being tagged.** Failure to do this can produce unpleasant surprises.

The more popular reactive forms of labels are those that bind to amino groups on proteins. Early in the game, fluorescein and tetramethylrhodamine isothiocyanates (FITC and TRITC) were among the most popular labeling reagents. Molecular Probes still sells isothiocyanate reagents, but recommends succinimidyl esters and sulfonyl halides because conjugates prepared using isothiocyanates reportedly deteriorate over time<sup>2332</sup>. **Research Organics** advocates dichlorotriazinylaminofluorescein (DTAF) as a replacement for fluorescein. Maleimide derivatives of labels react reasonably selectively with protein sulfhydryl groups.

The extremely high affinity of **biotin** for **avidin** or **streptavidin**<sup>300</sup> is widely exploited for labeling purposes. Labels may be covalently bound to avidin or streptavidin, and the labeled material used to detect biotinylated antibodies; alternatively, labels, especially larger molecules such as phycobiliproteins, may be biotinylated, and avidin or streptavidin then used to form a complex between the label and a biotinylated antibody. In some cases, at least, antibody-label complexes formed using a biotin-avidin reaction are stable enough to permit several complexes, each bearing a different antibody and a different fluorescent label, to be used simultaneously.

Maintaining activity of a labeled biomolecule may require the interposition of a third chemical structure, or **linker**, between the label and the molecule being labeled, particularly if the molecule itself is relatively small; I won't go into the details.

Having dwelt at length on the topic of labeling *per se*, we will now address the use of fluorescently labeled reagents for measurement of cell surface structures and properties.

## 7.6 IMPROVING SIGNALS FROM LABELS: AMPLIFICATION AND OTHER TECHNIQUES

In many cases, the cell- (or bead-) associated molecules we are trying to detect and quantify using a labeled reagent are abundant enough so that we can accomplish our task using **direct labeling**, incubating our cells or beads with a reagent bearing one or a few molecules of label, and then measuring the fluorescence intensity of the particles of interest in a cytometer, with or without a wash step to decrease the concentration of unbound reagent in the sample. When we are hunting rarer prey, we need to consider various ways of getting bigger signals from each molecule of interest than direct labeling can provide. In order to choose methodology appropriate to our measurement problems, we must appreciate several factors that potentially limit measurement sensitivity, and determine which of these are most relevant to our particular measurement problem.

The ultimate limit to sensitivity is set by the number of molecules of interest present in or on the particles we propose to analyze. Tomas Hirschfeld pointed out in the 1970's

that, once we are detecting and counting single molecules, or small numbers of molecules, we can expect fluctuations in the number of molecules in the observation volume to become a major source of statistical variance in quantitative measurements<sup>2657</sup>. Some 20 years later, when the sensitivity of their capillary electrophoresis detectors had reached the single-molecule level, Chen and Dovichi<sup>2658</sup> demonstrated the effect experimentally.

In the discussion of Q and B and their effects on measurement sensitivity (pp. 221-3), it was noted that a FAC-Scan or FACSCalibur, which, as flow cytometers go, has very efficient collection optics, will typically generate only a single photoelectron at the PMT photocathode for each four molecules (strictly speaking, for each four MESF) of phycoerythrin passing through the observation point; when fluorescein is detected, an average of 80 MESF must pass through the observation point to generate a single photoelectron<sup>2482</sup>. In these instances, measurements are limited by photoelectron statistics.

In a slow flow system such as the apparatus at Los Alamos used for DNA sizing and for single molecule detection of phycoerythrin, the observation time is much longer than in a conventional flow cytometer, and each MESF of phycoerythrin may generate a burst of 100 photoelectrons during its passage through the measurement system. If there are an average of 100 phycoerythrin molecules in the measurement system at any given time, they will give rise to 10,000 photoelectrons; the expected standard deviation would be 100 photoelectrons, and, in the absence of other sources of variance, one would be able to achieve a measurement CV of 1 percent. However, Poisson statistics would dictate that the standard deviation of the number of molecules in the measurement volume would be 10 molecules; the lowest possible CV is then not 1 percent, but 10 percent. Thus, what Chen and Dovichi<sup>2658</sup> define as “**molecular shot noise**” becomes the limiting factor in precision; in order to achieve 1% precision, one must measure or count at least 10,000 molecules.

These days, it is not uncommon to be able to detect a few hundred molecules of cell- or bead-associated antibodies or other target molecules in a conventional flow cytometer; while there may be fluorescence amplification techniques that let us collect hundreds of photoelectrons from thousands of molecules of a label for each target molecule present, they will not liberate us from molecular shot noise; we will, instead, come to recognize it as a major source of variance. Of particular interest is a recent paper by Elowitz et al<sup>2659</sup>, which considers molecular noise in the context of gene expression, noting that low intracellular copy numbers of molecules can limit the precision of gene regulation.

### Limits to Sensitivity: Autofluorescence

The spectral characteristics of covalent labels exert a significant effect on the sensitivity of flow cytometric measurements of weak fluorescence signals such as are obtained from cells stained with fluorescently tagged antibodies, hormones, lectins, etc. This is so because it is frequently not

instrument performance, but **cellular autofluorescence** that limits the number of labeled molecules detectable on or in cells.

As mentioned on pp. 216-7, the intensity of lymphocyte autofluorescence in the green spectral region used for fluorescein fluorescence measurement is the same as would be obtained from over 600 MESF of fluorescein. In most newer laser source instruments, this level of autofluorescence should be detectable above background.

There is, however, no way to use the green fluorescence signal alone to distinguish the proportions contributed by antibody or ligand fluorescence and autofluorescence. Consider two cells, one bearing no bound antibody and emitting autofluorescence equivalent to the emission from 1,000 fluorescein MESF, and the other bearing 300 MESF of fluorescein on cell-bound antibody or ligand and emitting autofluorescence equivalent to 700 fluorescein MESF. Both cells produce 1,000 fluorescein MESF at the detector. Good discrimination of stained and unstained cells will, therefore, require that several times as many fluorescein molecules as are detectable against zero background be present on the surface of the stained cells.

There is a potential problem with measurements of both sensitivity and autofluorescence, in that both are (or were) generally done using log amps, and both involve extrapolating a reference line calculated from measured values of fluorescence obtained from beads bearing known amounts of label. These known amounts typically range from 5,000 to 500,000 MESF, and PMT and instrument gains are generally adjusted to place peaks from the fluorescence distributions of labeled beads in the upper decades of a log scale. The blank beads used for sensitivity determination and the unstained cells used to determine autofluorescence levels fall at the low end of the scale, usually below 1,000 MESF.

When the regression line (see Figure 4-60 on p. 216) is calculated, a correlation coefficient and, in some cases, other measures of the distance from the line of the points representing labeled beads, are provided. If the correlation coefficient is low (low, in this instance, probably means less than 0.98, because we're working on a log scale), and/or the distances of the labeled beads from the line are large, it is fairly obvious that the log amp doesn't work all that well; the measured sensitivity and/or autofluorescence values are definitely suspect in such cases. However, all log amps become unreliable at some point in the lower region of their range, and good correlations and small distances of labeled beads from the regression line unfortunately provide no guarantee that the log amp is behaving at the level of the blank bead or the unstained cell. I have produced differences of several hundred MESF in measured sensitivity simply by interchanging log amps with DC offset levels differing by 1 or 2 mV. That's why I suggested (p. 217) that sensitivity and autofluorescence levels should be determined using a **linear fluorescence scale**, and that high-sensitivity quantitative fluorescence measurements also be done on a linear scale. I'll make the point again, because it's very important; if you're

trying to measure a few hundred molecules of bound antibody and you're not using a linear scale, you run the risk of discovering you've been kidding yourself in private by embarrassing yourself in public.

### Improving Sensitivity: The New Wave(length)

In cases in which cellular autofluorescence is a factor limiting sensitivity, one obvious way of improving sensitivity is to work with excitation wavelengths at which cellular autofluorescence is lower than it is when 488 nm excitation is used.

The excitation and emission spectra of autofluorescence reported for several mammalian cell types<sup>181,183</sup> are close to the spectrum of riboflavin (Fig. 7-7, p.291). Relatively little cellular autofluorescence is excited by light at wavelengths above 515 nm<sup>304</sup>, which are used for excitation of Cy3, tetramethylrhodamine, the rhodamine 101 derivatives XRITC and Texas red, Cy5, and the phycobiliproteins and tandem conjugates. Thus, the use of any of these labels can provide increased sensitivity for weak fluorescence measurements in mammalian cells.

The ratio of median emission from antibody-labeled cells to median emission from unstained cells, with both emission values expressed on a linear scale, can be taken as a measure of sensitivity; this figure was 10-15 times higher for cells stained with phycoerythrin-labeled antibodies and excited at 546 nm by the mercury arc lamp in an old B-D FACS Analyzer than for cells stained with fluorescein-antibodies and excited at 488 nm by an argon ion laser in a FACStar cell sorter (L. Lanier, M. Loken, N. Warner, personal communications and meeting presentations). While the FACScan has somewhat better PE fluorescence sensitivity than the FACStar, the analyzer, when using green excitation, remained superior<sup>180-1</sup>. The 532 nm line from a doubled YAG laser and the 543 nm line from a green He-Ne laser are usable for high-sensitivity, low autofluorescence measurements, although the low power levels (1-2 mW) available from green He-Ne lasers may limit sensitivity in practice. Since many more current instruments have red He-Ne or diode lasers than have green YAG or He-Ne lasers, it will usually be most practical to use allophycocyanin as a label with a red excitation source to make sensitive fluorescence measurements in mammalian cells without interference from autofluorescence.

If, however, one were interested in measuring cell surface antigens on *Synechococcus* or other species of cyanobacteria, a phycobiliprotein would be an extremely poor choice of label; cyanobacteria contain phycobilisomes stuffed full of phycoerythrin, allophycocyanin, etc., with the result that their autofluorescence, which is considerable, would be likely to swamp the signal from a phycobiliprotein label.

Vesey et al<sup>260</sup> provide a good example of how to select a label based on studies of the autofluorescence of particles of interest and of other particles and fluorescent solutes likely to be encountered in the sample; their target was *Cryptosporidium* oocysts in drinking water, and they found, using a

Coulter EPICS Elite flow cytometer, that phycoerythrin-, Cy-3-, or tetramethylrhodamine-labeled antibodies excited by a low-power Green He-Ne laser provided the best signal-to-background ratio for detection.

### Correcting and Quenching Autofluorescence

If your apparatus can discriminate between cellular autofluorescence and the fluorescence of your label, based on some difference in spectral characteristics, you may be able to pick out the label from the background.

If you happen to have a flow cytometer with two ion lasers, you can follow the lead of Steinkamp and Stewart<sup>780</sup>, who, using the multilaser flow cytometer at Los Alamos, took advantage of the fact that autofluorescence is better excited in the violet than at 488 nm (Figure 7-7), while fluorescein is very poorly excited by violet light. They made dual-beam measurements of cells stained with fluorescein-antibodies using a 413 nm beam from a krypton laser and a 488 nm beam from an argon laser, and subtracted a portion of the violet-excited fluorescence signal from the fluorescence signal excited at 488 nm.

Roederer and Murphy<sup>781</sup> devised a method applicable to flow cytometers with only a 488 nm excitation beam; they noted that, while green (530 nm) fluorescence in cells stained with fluorescein-ligands represented the sum of autofluorescence and fluorescein fluorescence, red (625 nm) fluorescence resulted almost entirely from autofluorescence; thus, by subtracting a portion of the red signal from the green signal, they could compensate for autofluorescence. This was done by digital computer processing of list mode data; Alberti, Parks, and Herzenberg<sup>782</sup> used the fluorescence compensation electronics in the FACS to perform similar manipulations on-line.

The methods described in the preceding two paragraphs allow you to compensate for autofluorescence relatively well on a cell-by-cell basis. If the issue is detecting populations of weakly stained cells above autofluorescence background, it may be sufficient to do histogram subtraction, an approach described by Corsetti et al<sup>1389</sup> and Müller et al<sup>1390</sup> (also see pp. 245-6)

A direct chemical approach to autofluorescence on a cell-by-cell basis was taken by Hallden et al<sup>1391</sup> and Mosimann et al<sup>2661</sup>, who, respectively used crystal violet and trypan blue to quench intracellular autofluorescence, allowing detection of surface antigens with fluorescein-labeled antibodies and of fluorescein-labeled nucleic acid probes.

The bottom line here, however, is that none of the methods just described deal as effectively with autofluorescence as does choosing a label and an excitation and emission wavelength at which autofluorescence is minimal.

### Raman Scattering Effects on Sensitivity

Phycoerythrin offers an attractive alternative to fluorescein when extreme sensitivity is required, because it becomes possible to decrease the effect of cellular autofluorescence, as well as to place a large number of fluorescent

chromophores on each antibody molecule. When PE is excited at 488 nm, rather than above 515 nm, cellular autofluorescence is not decreased. Moreover, there is the potential for interference from **Raman scattering** (p. 118), which occurs when a molecule undergoes a vibrational transition while scattering light. Raman emission is most likely to be at a frequency that is the sum of the frequencies of the incident light and the vibrational transition. The frequencies are expressed in **wave numbers** ( $\text{cm}^{-1}$ ), which are the number of wavelengths per centimeter; the relationship between wavelength  $\lambda$  in nm and frequency  $\nu$  in  $\text{cm}^{-1}$  is  $\nu = 10^7/\lambda$ . In flow cytometry, the dominant transition involved in Raman scattering comes from stretching of O-H bonds in water, at around  $3600 \text{ cm}^{-1}$ . At 488 nm, or  $20492 \text{ cm}^{-1}$ , the Raman emission is at  $16892 \text{ cm}^{-1}$ , i.e.,  $10^7/(20492 - 3600)$  nm, or 592 nm, a wavelength that may be transmitted by filters used for PE fluorescence measurement. When excitation at 532 nm is used, Raman emission is at 658 nm, which should not interfere with measurement of PE fluorescence but which could interfere with measurements of a PE-Cy5 tandem conjugate. Water Raman frequencies for various excitation wavelengths appear in Table 7-4 below.

EXCITATION (nm)	H.O RAMAN EMISSION (nm)

Table 7-4. Raman emission from water.

In extremely high-sensitivity fluorescence measurements using single photon counting, broadband Raman emission, at wavelengths other than those tabulated above, may be the limiting noise source<sup>144</sup>.

### Increasing Sensitivity: Amplification Techniques

Since experimenters can't readily change the number of molecules of the molecules they're trying to find in or on cells, they often attempt to shift the odds in their favor by

increasing the amount of label that will be hung on each target molecule.

Some flow cytometer users have the option of increasing illumination power; few have the option of increasing light collection efficiency, and, while you can always try to find a PMT with more sensitivity than the one you have, there is a limit to how much measurement sensitivity can be increased by going that route. When increasing excitation power or fluorescence collection or detection efficiency will not improve measurements, increasing the number of fluorescent molecules bound per molecule of antibody or ligand using an amplification technique may be the only option available.

### Amplification by Indirect Staining

The simplest way to do this in the context of immunofluorescence measurements is by using **indirect staining**; approximately six molecules of a polyclonal secondary **developing** antibody can be bound to each molecule of primary antibody used, putting six times as many molecules of label at each antigenic site as would be there if a directly labeled antibody were used. There are a number of variations on the basic theme.

Cohen et al<sup>178</sup> approached the problem of detecting small numbers of cell surface receptor sites by devising what they termed the "**super avidin-biotin system**" (SABS). Biotinylated antibodies bound to receptor sites are reacted, in succession, with phycoerythrin-streptavidin, with biotinylated anti-streptavidin antibody, and again with phycoerythrin-streptavidin. The SABS system reportedly allows quantification of antigenic sites within the range of 100-1300 sites per cell; as few as 50 sites/cell can be detected, a sensitivity approaching that of conventional radioimmunoassay.

Zola et al<sup>1380-1</sup> used a somewhat simpler technique, in which a primary mouse monoclonal antibody was developed with a horse anti-mouse antiserum that was then labeled with a phycoerythrin-streptavidin conjugate; they could reliably detect 100 primary binding sites, and applied their methodology to quantification of cytokine receptors.

### Amplification Using Labeled Particles

A greater degree of amplification than is possible with indirect staining may be achieved by attaching antibodies (at other than their specific binding sites) to **larger particles**, among which are included fluorescently tagged **viruses**, **membrane microvesicles or liposomes**, **bacteria**, and **plastic beads** (typically coated with antibody, antigen, hormones, etc.) as cell surface labels. Quantum dots (pp. 339-40) also fit into the particle category. Problems with clumping, nonspecific binding, and endocytosis of labeled particulates can occur when this approach is taken, and caution is therefore advisable.

Truneh et al<sup>777,1382</sup> described the use of **unilamellar liposomes** containing **carboxyfluorescein** or sulforhodamine, and conjugated to **protein A**, for detection of small numbers of receptor sites on cell surfaces. Carboxyfluorescein diffuses

out of liposomes extremely slowly, and therefore provides a relatively stable internal label for these structures. Gray et al.<sup>383</sup> also reported successful use of the carboxyfluorescein liposome technique. However, the sensitivities achieved are probably matched by modern instruments in analyses of samples stained only with directly labeled antibodies.

I have also already mentioned (p. 277) the use of a **non-fluorescent particle label, colloidal gold**<sup>708</sup>, which can be conjugated to antibodies and other ligands and detected on cells by the change in their light scattering characteristics. Antibodies coupled to small (0.1-0.5  $\mu\text{m}$ ) nonfluorescent polystyrene beads can also be detected when bound to surfaces by strongly increased side scatter signals<sup>2662</sup>. Siiman et al.<sup>2663</sup> were able to detect the binding of two different antibodies, one bound to a polystyrene bead coated with colloidal gold or silver and the other bound to an uncoated polystyrene bead, to cells using measurements of light scattering at 10-20° and at 20-65°; different wavelengths were needed for maximum discrimination of populations depending on whether colloidal gold or silver was used.

While nonfluorescent particles and/or colloidal silver/gold labeling probably do not provide a substantial increase in sensitivity over what can routinely be obtained using direct fluorescence measurements, they do make it possible to detect cell- or bead-bound antibodies in instruments using less expensive light sources and detectors than are needed in most fluorescence flow cytometers.

**Phycobilisomes** (p. 335), with molecular weights in excess of 10,000,000, might be thought of as biological particles; when directly or closely linked to antibodies, they appear to sterically hinder binding to cell surface antigens. However, Telford et al.<sup>2664</sup> found that a red-excited stabilized phycobilisome coupled to streptavidin via a spacer (PBXL-3L, Martek) provided substantial amplification when compared to APC-streptavidin in labeling cell-bound biotinylated antibodies.

### Amplification Using Enzymes as Labels: Playing the Hole CARD

A classical amplification technique applicable (originally with some difficulty) to flow cytometry is that of **enzyme-linked assay**. A ligand that reacts specifically with the substance sought by the experimenter (the chemists call the substance sought the **analyte**, which has always sounded kinky to me) is conjugated to an enzyme; after excess ligand-enzyme is removed, the analyte-ligand-enzyme complex is detected by reaction with a **chromogenic** or **fluorogenic substrate**, a colorless material that is acted upon by the enzyme to form a colored or fluorescent product. Once this reaction is complete, thousands of molecules of detectable product are present in the vicinity of each molecule of analyte.

Because of its large amplification factor, enzyme-linked assay offers high sensitivity, and is particularly useful for detection of small amounts of antigens and small numbers of copies of specific genetic sequences in cells; the obstacle to

the application of the technique in flow systems is the necessity to trap the reaction product of the enzyme reaction in the cells being analyzed. Technicon (now Bayer Diagnostics) did this successfully in the Hemalog<sup>84,5</sup> and H-1 series of hematology analyzers, which use absorption measurements to identify neutrophil and eosinophil leukocytes by the presence of peroxidase in their specific granules. Kim et al adapted **immunoperoxidase**<sup>779</sup> and **alkaline phosphatase**<sup>1384</sup> labeling techniques for use on the Technicon instruments to subtype lymphocytes; the results based on forward scatter and absorption measurements were comparable in speed, sensitivity, and accuracy to those obtained by fluorescence flow cytometry.

In 1989, Bobrow et al.<sup>2665-6</sup> described the technique of **catalyzed reporter deposition**, now familiarly known as **CARD**, which has since facilitated enzyme-based amplification in flow cytometry. The analyte of interest (e.g., an antigen) is reacted with an appropriate reagent (e.g., an antibody) conjugated with horseradish peroxidase (HRP). The specimen is then reacted with a phenolic HRP substrate (e.g., tyramine). HRP action on tyramine yields a highly reactive species that binds covalently to proteins. The tyramine may be labeled with biotin, as done in the original publication, and its presence demonstrated by subsequent reaction with fluorescent labeled streptavidin<sup>2667-70</sup>. However, it is becoming more common in current practice to label the tyramine directly with a fluorescent dye<sup>2332,2671</sup>. In either case, many fluorescent labeled molecules of the tyramine reaction product will accumulate, and stay, in the region of each reagent-analyte complex. Multiple rounds of amplification are possible, using HRP-labeled antibodies against the label deposited in the first CARD stage. Tyramide amplification reagents and kits for flow cytometry, using biotin, as developed by Kaplan et al.<sup>2669-70</sup>, are available from **Flow-Amp, Ltd.**; Molecular Probes offers a line of reagents including both biotinylated and fluorescent dye-labeled tyramine<sup>2332</sup>. Molecular Probes also offers an enzyme amplification technology described as **Enzyme-Labeled Fluorescence (ELF)**; antibodies or other reagents are tagged with alkaline phosphatase, either directly or via a biotin-streptavidin reaction, and the ELF 97 phosphatase substrate is added, forming a bright green fluorescent, insoluble precipitate in the vicinity of the antigen or analyte molecules of interest<sup>2337</sup>.

### Amplifying the Analyte: The Polymerase Chain Reaction (PCR)

An enzyme-based amplification method to which we will return in a later section is the **polymerase chain reaction (PCR)**, which can be used to produce multiple copies of a known genetic sequence *in situ* for detection using labeled probes, amplified or otherwise.

### Amplification Techniques: Pros and Cons; Fluorescent vs. Nonfluorescent Labels

Since the fairly simple and straightforward modifications of the **indirect staining** technique described above have

permitted measurement of as few as 100 binding sites on cells, it is not clear that using larger labeled particles for amplification will further improve sensitivity.

Enzyme amplification is particularly useful in that it can allow qualitative analyses of small amounts of analytes in cells and tissues to be done with chromogenic substrates and a simple transmitted light microscope. As was mentioned on p. 77, the first approaches to antibody labeling involved conjugation of antisera with azo dyes; however, complexes of tissue antigens with such dyes, even in relatively high concentrations, exhibited only weak coloration under the light microscope. This led Coons, Creech, and Jones<sup>44</sup> to turn to fluorescent labels, which were more readily detectable at low concentrations against the darker background present in a fluorescence microscope. Enzyme-linked immunoassay achieves what simple labeling cannot.

Most fluorescence flow cytometers have neither absorption nor extinction measurement capabilities, and are therefore not well equipped for measurement of the reaction products of chromogenic substrates, although forward and right angle scatter measurements may be usable under some circumstances. Enzyme-linked methods have therefore, to date, been used principally with transmitted light microscopy and with static and image cytometry, and are probably in wider use than is fluorescence flow cytometry.

On one of my occasional descents from my ivory tower, I heard a real pathologist give a highly sophisticated talk on lymphomas, involving detection of multiple antigens, *in situ* hybridization with genetic probes, PCR, etc. Flow cytometers weren't involved; all the work was done using enzyme-linked reagents, and much of it was done on tissue slides, where the objective was to determine anatomical localization of various things, a task to which flow cytometers are, and will, for the most part, remain, unsuited. The semiquantitative analyses available from microscopic observation were all that was necessary to answer the biological questions at hand. I'm sure some of the work could have been done using fluorescence flow cytometry, but it wouldn't have been done any better, cheaper, or faster. Food for thought.

Coventry et al<sup>2672</sup> used video image analysis to compare the detection sensitivity of immunoperoxidase staining on slides with that of flow cytometry; they found that detection of 100-200 cell surface molecules in specimens on slides was possible only if heavy metal-enhanced immunoperoxidase methods were used, while high-sensitivity flow cytometric methods<sup>1380-1</sup> could, in some cases, detect as few as 50 molecules.

To some extent, amplification increases sensitivity at the expense of precision, because amplification factors aren't exact; you won't get exactly six molecules of developing antibody per molecule of primary antibody, or 100,000 molecules of product per molecule of enzyme-linked antibody. If you're looking for 100 copies of something, however, you have Poisson sampling statistics and molecular shot noise<sup>2658</sup> (p. 341) working against you, anyway. Even if you hung a 2

mW diode laser on each molecule, you'd still count only 100 molecules, and the measurement CV could be no less than 10 percent.

### Improving Sensitivity: Time-Resolved Fluorescence

On p. 283, it was mentioned that phase-sensitive detection of a fluorescence signal in a flow cytometer using a modulated light source could discriminate fluorescence signals from different materials with different fluorescence lifetimes. The lifetimes of most of the materials responsible for autofluorescence are on the order of tens of nanoseconds; if one uses a label with a substantially longer lifetime, and a light source emitting brief (picosecond or shorter) pulses, and delays the fluorescence emission measurement for 50 nsec or so following the pulse, the contributions of autofluorescence and of other interferences, e.g., Raman scattering, stray scattered light, and filter fluorescence, are eliminated from this **time-resolved fluorescence** signal. Chelates of rare earth metals such as europium and terbium have fluorescence lifetimes on the order of microseconds (see p. 113), and Bob Leif suggested in the 1970's<sup>1110</sup>, as did Tomas Hirschfeld (personal communication), that they might be useful as labels for time-resolved flow cytometry with pulsed sources. Condrau et al<sup>1385-6</sup> described measurements of cells bearing europium-chelate labeled antibodies in a modified flow cytometer in which acousto-optic modulation is used to deflect the illuminating beam away from the flow cell once a scatter signal is detected; their papers also include good bibliographies on time-resolved fluorescence immunoassays. Related work by Beverloo et al<sup>1387-8</sup> describes the use of **phosphor particles** as luminescent (in this case, phosphorescent rather than fluorescent) labels for time-resolved image cytometry. One drawback to both rare earth chelates and phosphors as labels in the context of flow cytometry is the long measurement time required to take advantage of long excited state lifetimes, which run to hundreds of microseconds; this would limit throughput to a few hundred cells/sec, but the tradeoff may be worthwhile if extreme sensitivity is required.

## 7.7 MEASURING CELL SURFACE AND INTRACELLULAR ANTIGENS

Almost all of the fluorescence flow cytometers now in use have been applied, at one time or another, to measurements of **cell surface immunofluorescence**. The desire to do immunofluorescence measurements motivated researchers and clinicians to learn about flow cytometry and buy flow cytometers; and this legitimized other flow cytometric techniques not based on immunofluorescence, such as DNA analysis and differential leukocyte counting.

The literature on flow cytometry of immunofluorescence is so vast that I will not even attempt to summarize the fraction of it that I have seen. Instead, I'll try to present the basics and to touch on some issues that I don't think have been well covered elsewhere.

## History and Background

In the late 1960's, when most of the few people involved in flow cytometry were looking at DNA stains and trying to tell normal from abnormal cells in cervical cytology specimens, Len Herzenberg alone had the vision to appreciate that the combination of the apparatus and fluorescent antibody reagents could unravel the genealogy and developmental history of the lymphocytes.

Within a few years, flow cytometry, predominantly in the form of gated single-parameter immunofluorescence measurements, and cell sorting and subsequent functional analysis, had been used to define a taxonomy of lymphocytes, in mice and men, where none had existed previously. The methodology that Herzenberg and his associates and students had used to study murine cells was adapted and aggressively applied to human immunology by Stuart Schlossman in the United States, Melvyn Greaves in Great Britain and a rapidly growing crowd of others.

This first wave of activity was all the more remarkable because it occurred several years before the discovery of monoclonal antibodies; the identification and preparation of both reagents and samples were considerably more complicated than they are today. While immunologists, even in those days, seemed to have the opinion that fluorescent antibodies were the only specific reagents, and that neither cytochemistry nor multiparameter flow cytometry would have any use in future work on blood cell development, differentiation, and pathology, this viewpoint was not justified then; subsequent history has eroded any remaining basis for it.

Obviously, antibodies were exquisitely specific, but, until the advent of **monoclonal antibodies**<sup>785</sup>, you could never be sure for what they were so specific, and never count on getting a serum with quite the same specificity next time you bled the same animal. For you physicists and electronics out there (bear with me, immunologic sophisticates), I should amplify on this a bit.

### Monoclonal Antibodies for the Uninitiated

For the past few hundred years, or since before anybody knew there were lymphocytes, we have been in the business of deliberately inducing **immunity** to various diseases in humans and animals, by injecting material from organisms that cause those diseases (or, sometimes from organisms closely related to the disease-causing organisms). The substance injected is called an **antigen**. If, a week or more after the antigen is injected, you extract some blood serum from the animal (or human) that received the antigen, you can (usually) demonstrate formation of a precipitate if antigen is added to the serum, due to the formation of complexes between molecules of antigen and molecules of serum proteins called **immunoglobulins (Igs)**, which are the **antibodies**.

Immunoglobulins are produced by **B lymphocytes**; in order for such production to occur, the concerted action and interaction of **T lymphocytes** and other blood cells called **macrophages** is also required. There are several different

classes of Igs; B cells start out producing a very large molecule called IgM, and then typically switch to producing IgG, IgE, which is involved in allergic reactions, represents another class of Igs. The **gamma globulin** and **antitoxin** or **antiserum** that some of us remember being used in medicine and others have encountered in old novels are serum immunoglobulin fractions. All Igs of a given class have relatively similar "backbone" structures, but, at some points in these molecules, there exist **variable regions** that differ from molecule to molecule in amino acid composition and sequence; it is the variable regions that react with antigen. Also, Ig molecules are **multivalent**, i.e., each molecule contains at least two sites capable of binding antigen.

Antibodies react with antigens in a very specific fashion and, typically, with very high affinities, but a conventional antiserum contains not one type of Ig molecule with one unique structure, but a large number of antibodies, with different molecular structures, each reacting with different affinity with a different chemical group on the antigen. Lymphocytes, in the course of their development, undergo **gene rearrangement** of the genes that encode the variable regions of Igs; this "shuffling" of genetic material insures that there will be a great diversity of amino acid sequences, and therefore of reactivities, represented in the B cell population of any given individual, although any given B cell can produce only one specific molecular structure. B cells normally carry Igs around on their cell surfaces; when the **surface membrane immunoglobulin (SmIg)** on a B cell binds to an antigen, it stimulates the B cell to reproduce.

Thus, when an animal is **immunized**, or injected with antigen, B cells that produce, and bear on their surfaces, Igs that react with that antigen reproduce. Each B cell forms a **clone** of progeny, all of which produce Ig molecules with the same structure, which is different from the structures of the Igs produced by all the other clones. The antiserum is therefore described as **polyclonal**. Polyclonal antisera, by their biological nature, contain a small fraction of mixtures of Igs that react, with differing affinities, with different determinants on the same antigenic molecule, as well as a larger fraction of "irrelevant" antibodies which, while they may be very relevant to protecting the organism from infections, don't react at all with the antigen the experimenter injected to produce the antiserum, but may react with any of a tremendous variety of other proteins or macromolecules foreign to the animal in which the antiserum was produced.

If you extract the immunoglobulin fraction of an immunized animal, you end up with a number of Ig molecules that will react specifically with the antigen you're after and a much larger number of Ig molecules that will react with other things. **Adsorption**, or reaction with materials containing these irrelevant antigens, can be used to remove some of the irrelevant antibodies, and **affinity purification**, which traps desired antibodies on a column or other substrate containing **immobilized antigen**, can further increase the specificity of a polyclonal antiserum – to the point at which as many as a few percent of the Ig molecules will react with

antigen! Even at this rather shocking level of impurity, specificity may be sufficient to permit definition of the chemical structures on or in cells with which a polyclonal antiserum is reactive.

In the days before monoclonal antibodies, this was what had to be done before one could even think of using an antiserum for immunofluorescent staining; the whole process seemed more art – many would say black art – than science. For those of us who worked in industry, the difficulties of obtaining and/or standardizing immune reagents were a major obstacle to the development and dissemination of procedures involving immunofluorescence. Very few people envisioned a need for more than two immunofluorescent labels; it was hard enough to do single-color fluorescence, and two colors represented a *tour de force*.

Things changed dramatically for the better in the late 1970's, with the dissemination and refinement of methods for **monoclonal antibody production**<sup>785</sup>. If you have the opportunity to look at a copy of the First Edition of *Flow Cytometry and Sorting*<sup>2</sup>, which was published in 1979, you can try to find the single appearance of the words “monoclonal antibodies” in that book's 716 pages. They are not, by the way, found in any of the chapters that deal with applications of flow cytometry to immunology.

**Monoclonal antibodies** are produced by forming hybrids between B cells from animals immunized with an antigen and cultured cells derived from B cell tumors. The tumor cells, unlike normal B cells, are **immortal**, i.e., they can be grown in culture for generations on end. The hybrid cells acquire the property of producing one molecular species of Ig with one specific reactivity from their normal B cell parents, and the ability to grow indefinitely from their malignant parents. Cultures can be started from a single hybrid cell; these will thereafter continue producing identical Ig molecules as long as the culture is maintained.

Monoclonal antibodies are, thus, very well defined, in terms of their own structure, and one can be pretty well sure that all of the Ig molecules in a monoclonal will react with the same site on the antigen with the same affinity. However, if the structure of a given cellular antigen is unknown, simply having a monoclonal antibody instead of a polyclonal antiserum against the antigen doesn't tell you any more about the structure, although it may make it operationally easier to elucidate that structure.

### Cell Surface Antigens: Structure versus Function

It was obvious to some people long ago that antigens weren't present on cell surfaces simply for decoration, or as Nature's bar code, but, rather, that each antigen had a function, so that, in most cases, **one person's surface antigen is another person's receptor**. This is much better and more widely appreciated in 2003 than it was in 1978. Monoclonal antibodies have, in fact, greatly facilitated studies of receptor-ligand interactions, in which considerations of specificity formerly demanded use of labeled natural ligands; the antibodies can be made with higher affinity and the structure on

the receptor to which they bind can be selected to a great extent.

The advent of monoclonals also eliminated most of the difficulties associated with reaction of cells with two or more antisera to demonstrate two or more discrete antigens on or in the cells; this, in turn, awakened interest among immunologists in increasing the number of available antibody labels. The 1977 publication by Loken, Parks and Herzenberg on two-color immunofluorescence using fluorescein and tetramethylrhodamine as labels with argon ion laser excitation<sup>115</sup> made it clear that improvements in labels and reagents, as well as in equipment, would be necessary to make multicolor work generally feasible.

### Moving Toward Multicolor Immunofluorescence

The improvement in labels began with the development of the long-wavelength rhodamine 101 dyes XRITC and Texas red, and continued with the introduction of the phycobiliproteins and, later, of tandem conjugates. While XRITC and Texas red forced some improvement in equipment, by mandating the use of dual-wavelength excitation, the improvement increased the cost and complexity of apparatus. The phycobiliproteins and tandem conjugates have since made multicolor fluorescence easily accessible to immunologists and other workers without the need for much specialized training in instrumentation.

The expanding armamentarium of monoclonal antibody reagents and labels precipitated some changes in immunologists' attitudes; they had enough and good enough reagents to do multiparameter analysis and, now that they had more than two parameters to keep track of, they had adequate motivation to use computers for data analysis and storage. Without computerized data analysis systems, it is unlikely that two-color, let alone three- and four-color immunofluorescence measurements, would have become commonplace.

In retrospect, I should not have expected that immunologists would take kindly to my glib suggestions in the mid-1970's that they run out and do 3-color and 4-color immunofluorescence measurements using multiple excitation beam, multiparameter flow cytometry. Most immunologists were unaware, as I was aware, of the existence of the hardware and software technology required, and painfully aware, as I was unaware, of how difficult it was to produce even good two-color immunofluorescent staining using conventional antisera and the flow cytometers that were then generally available. We literally could not give away a multiple beam apparatus in the mid-1970's; times have certainly changed.

While the demonstration in 1979 of two-color immunofluorescence using dual-laser excitation of fluorescein and XRITC generated a substantial demand for dual-laser instruments, a look at the literature reveals that the number of papers involving fluorescein/XRITC or fluorescein/Texas red immunofluorescence published during the 5 years after the apparatus and labels became available was considerably smaller than the number of dual-laser flow cytometers pur-

chased with such studies in mind. Clearly, multicolor immunofluorescence was harder than it looked.

In the 1980's, history repeated itself, as people stam-peded after flow cytometers with CW dye lasers, which could allow them to do 4-color immunofluorescence, using an argon laser at 488 nm to excite fluorescein and phycoerythrin, and a dye laser at 600 nm to excite Texas red and allophycocyanin, provided reagents were available. Some settled for 3-color immunofluorescence, which could be done with a single beam, using fluorescein, phycoerythrin, and phycoerythrin<sup>305</sup> or a phycoerythrin-allophycocyanin<sup>306</sup> or phycoerythrin-Texas red tandem conjugate. The first couple of years' worth of publications and presentations actually demonstrating 3-<sup>317,320</sup> and 4-color (L. Herzenberg et al, personal communications and meeting presentations) immunofluorescence using the labels just mentioned came either from Herzenberg's laboratory at Stanford or from B-D's antibody production facility. This was strong evidence in favor of the view that **access to and skill in the use of reagents, and not access to hardware, were the most critical contributing factors to success with multicolor immunofluorescence measurements.**

Today, phycobiliprotein and tandem labels, an unbelievably wide selection of monoclonal antibodies, and instruments that can measure eight or more colors of fluorescence, are available and easy to use compared to what came before. Access is much less of a factor than skill.

### Antibody Reagents and Staining Procedures

Most of us, myself included, don't make or conjugate our own **antibodies**; whatever isn't supplied by our collaborators has to be scrounged or bought. Once you get past the realization that there are few commodities you can legally buy that cost as much per small vial, you can appreciate the good points of commercial monoclonal antibodies. They are generally well-defined and well-controlled, you can get them with a variety of labels attached, and you generally can find out how much to use to stain how many cells by reading the label or package insert. Commercial polyclonal antisera, adsorbed and/or affinity-purified or otherwise enriched in antibodies for the antigens you're after, are also available and relatively convenient to use.

Susan Sharrow, who worked with both flow cytometers and monoclonals at NIH more or less since the inception of each, took me to task years ago for suggesting that it was easier to make flow cytometers than monoclonals. It's gotten easier to do both; hybridoma clones are available from places like the American Type Culture Collection, and you can buy kits for purifying the immunoglobulin fraction and labeling the antibodies. Given the range of monoclonals available, labeled, off the shelf, most people won't have to roll their own. We did do it in my lab once, just for the experience.

### Antibody Fragments versus Antibodies as Reagents

For some applications, it is preferable to use enzymatically cleaved antibody **fragments** instead of the whole im-

munoglobulin molecule. Certain cells, e.g., macrophages, monocytes, and granulocytes, have surface receptors that bind the **Fc** portion of antibodies more or less independently of the antigenic specificity of the antibodies; these cells may, by this mechanism, therefore be stained by labeled antibodies to antigens that are not present on the cell surface. Enzymes can be used to produce **monovalent (Fab)** or **bivalent (F(ab')<sub>2</sub>) antigen binding fragments** that will not bind to Fc receptors, eliminating the problem of nonspecific staining. The Fab fragments are useful in situations in which it is necessary to avoid crosslinking of antigenic sites and/or agglutination, although their binding affinities are lower than those of the multivalent antibodies from which they are derived. Fragments of some antibodies are available off-the-shelf, with or without fluorescent labels.

### Engineered Antibodies: Phage Display and scFvs

It is now possible to produce monoclonal antibodies, human as well as murine, without benefit of either immunization or hybridoma technology, using **phage display**. It was shown in the late 1980's that proteins coded for by gene sequences introduced into the genome of filamentous bacteriophages could be expressed on the surface of the virions<sup>2673</sup>; it was also demonstrated<sup>2674,5</sup> that a functional antibody variable region (**Fv**) could be expressed in the periplasmic region of *E. coli* into which genes coding for the variable regions of both light and heavy immunoglobulin chains had been introduced. In 1990, McCafferty et al<sup>2676</sup> described production of active antibody molecules in filamentous phage.

The technology has since come a long way; there now exists a phage display library of  $2 \times 10^9$  members, about three-fifths of which code for functional human **single chain variable fragments (scFvs)**; it is possible, with a minimum of additional genetic manipulation, to derive Fabs and immunoglobulins with the specificity of the scFvs<sup>2677</sup>. Clonal selection has become the province of biotech companies; using appropriate gimmicks (including cell sorting), you can grow up a potful of monoclonal antibody to the antigen of your choice, starting, if you like, with a single B cell<sup>2678</sup>. Since you can hold the light and heavy chain portions of an scFv together with a synthetic linker, you can add things on to the linker, producing such goodies as antibodies tagged with alkaline phosphatase<sup>2679</sup> or GFP<sup>2680</sup>, or high-avidity tetrameric antibodies<sup>2681</sup>.

Much of the current work on engineered antibodies is focused on development of agents that can be used to treat human disease, rather than on expanding the repertoire of reagents for cytometry, but it's a safe bet that we'll get some interesting things to play with during the next few years.

### Molecular Probes' Zenon Antibody Labeling

Some lower-tech, although not less interesting, antibody engineering is involved in a new methodology for antibody labeling recently developed by Molecular Probes<sup>2332</sup>, which they call Zenon technology. The Zenon One Mouse IgG, labeling kits incorporate purified Fab fragments of a goat

antibody to the Fc portion of mouse IgG<sub>1</sub>; the Fab fragments are available with any of a number of labels, including fluorescent dyes, phycobiliproteins and tandems, biotin, and enzymes, covalently attached. A Zenon One Fab reagent can be used to label a very small amount (1 µg or less) of a mouse monoclonal antibody; after 10 minutes incubation, any unbound labeling reagent is, in essence, inactivated by addition of an excess of indifferent mouse IgG<sub>1</sub>. Multiple antibodies labeled with different dyes can be used together, and quantitative measurements are possible, although the excess indifferent antibody added to remove unreacted labeling reagent will, over a period of hours, remove some reagent from the antibodies of interest. The Zenon methodology should be particularly helpful to investigators developing their own monoclonal antibodies, as it should facilitate simultaneous analysis of two or more antibodies on cells.

### Antibody Shelf Life and Quality Control

Antibodies keep pretty well, but they don't have an infinite shelf life. You need to keep an eye out for crud accumulating in your vials of antibody, spinning down aggregates and so on when bad things happen to good antibodies. Periodic measurement of the fluorescence intensity of antibody bound to beads with known binding capacities allows you to monitor reagent quality. Manufacturers usually tell you how many milligrams of antibody protein are in the vial, which may be helpful; they don't usually tell you how many molecules of label are on each antibody molecule, which would also be helpful.

### Direct Staining Using Monoclonal Antibodies for 2, 3, and More Colors with 488 nm Excitation

To my way of thinking, the best way to proceed when doing immunofluorescence is the way that requires the least work. I use monoclonal antibodies whenever I can get them, and, unless I'm looking for an antigen that is scarce enough to force me to employ some kind of amplification procedure (pp. 343-5), I prefer to stain using antibodies with directly conjugated labels. Most people, myself included, have tended to use fluorescein on the first antibody and phycoerythrin on the second. Fluorescein is available on more antibodies than phycoerythrin, and fluorescein-labeled antibodies are usually cheaper; however, phycoerythrin is a better label in the sense that it is brighter on a per-molecule-of-antibody basis (see Figure 1-18, p. 37). The figure also indicates that, for 3-color work with 488 nm excitation, PE-Cy5 tandem conjugates are preferable as labels to PE-Texas red tandem conjugates, because there are fewer spectral overlap problems with phycoerythrin. Four-color immunofluorescence with a single 488 nm beam once pretty much forced you to use PE-Texas red conjugates, although phycocyanin conjugates were reported usable if the antigen density was high enough<sup>75</sup>. These days, you have PE-Cy5.5, PerCP-Cy5.5, and PE-Cy7 to play with, and you can do 7-color immunofluorescence using a 488 nm beam if you've got the right instrument.

### Multicolor Work Using Multiple Lasers; Biotin-Avidin Labeling

If you have a second laser emitting at 590 nm or above, i.e., a CW dye laser, a red He-Ne laser, a krypton ion laser, or a visible diode laser, in addition to a 488 nm argon laser, it may make sense to use allophycocyanin even as a third label, because compensation should not be necessary. Lanier, Loken, and others at B-D<sup>78-8</sup> did a lot of serious, big-league three-color immunofluorescence in this fashion with fluorescein, phycoerythrin, and allophycocyanin, using an argon laser emitting about 100 mW at 488 nm to excite the first two labels and a He-Ne laser emitting under 50 mW at 633 nm to excite the third. Hoffman et al<sup>66</sup> did 5-color measurements using phycocyanin and allophycocyanin B as labels with 633 nm excitation, and fluorescein, phycoerythrin, and a PE-Texas red conjugate excited by a second 488 nm beam; these days, you'd probably choose APC, APC-Cy7, and APC-Cy5.5, in that order, as red-excited labels.

Three-laser instruments are more common than they used to be, and, in the future, we can expect the most common three-beam systems to use 488 nm argon or solid-state lasers, red He-Ne or diode lasers, and violet diode lasers; Cascade blue and cascade yellow, or materials with similar spectra, are probably the best bets as labels for immunofluorescence when using violet excitation.

### Mixing Colors: Do's and Don'ts

It helps to consider in advance which labels you'll want on which antibodies. One of the more general rules with which you contend in flow cytometry is that, when you have equal intensities of fluorescence coming from two materials excited at the same wavelength, it's easier to eliminate interference in the shorter wavelength signal from the longer wavelength fluorescent material than to eliminate interference in the longer wavelength signal from the shorter wavelength fluorescent material. This is so because the emission spectra of most materials are skewed toward longer wavelengths; the "red tail" of fluorescein emission, for example, overlaps a substantial part of the phycoerythrin emission spectrum, while there is very little overlap between the shorter wavelength portion of the phycoerythrin emission spectrum and the peak region of the fluorescein emission spectrum. Thus, you should use fluorescein to label the antibody that will give the weaker signal; this will also minimize crosstalk between fluorescein and phycoerythrin immunofluorescence signals, so you will need less fluorescence compensation.

The same argument applies with even greater force when you are considering combining immunofluorescent stains with other dyes that produce very strong fluorescence signals, e.g., nucleic acid dyes. The weak fluorescence of fluorescein-labeled antibodies can be discriminated fairly effectively from propidium fluorescence, although some overlap compensation is advisable; it would be much more difficult to discriminate phycoerythrin fluorescence from that of a

nucleic acid dye such as TO-PRO-1. While phycoerythrin and propidium fluorescence emissions overlap considerably, Corver, Cornelisse, and Fleuren<sup>1392</sup> have shown that phycoerythrin antibody fluorescence can be discriminated from propidium fluorescence at levels above about 50,000 antibody binding sites per cell, making measurement of DNA and two antigens possible on a 3-color instrument.

Since the emission spectrum of fluorescein and the absorption spectrum of phycoerythrin overlap, **energy transfer** from fluorescein to phycoerythrin will occur and, if fluorescein and phycoerythrin molecules are in close proximity, may be significant. This will result in lower fluorescein fluorescence intensity than would otherwise be expected. Chapple, Johnson, and Davidson<sup>1393</sup> showed, by dual labeling of cells with pairs of monoclonal antibodies, that R-phycoerythrin could quench fluorescein emission when both were attached to the same cell. If quantitative or semiquantitative information is important, it is advisable to compare intensities of one- and two-antibody control samples to determine the extent of quenching. It is also important to note that fluorescence compensation won't work properly when there is substantial energy transfer; this will interfere with quantitative measurements, and, in the most critical cases, it may be desirable to use multiple illumination beams for accurate quantification.

### Cocktails for Five: Multiplex Immunofluorescence

In practice, there are numerous situations in which the identification of multiple, discrete cell subpopulations is of primary importance, while quantification is either secondary or not necessary.

The relative ease with which cell samples can be stained using mixtures of monoclonal antibodies has led to the independent development by several groups of immunofluorescence staining techniques involving **multiplex labeling**, which may allow demonstration of three or more antigenically distinct cell populations in a single sample using only two fluorescent labels, offering considerable savings of time and labor compared to conventional staining techniques.

Definition and counting of subpopulations in mixed populations, as in lymphocyte subset analysis, is most easily and most commonly done by using antibodies that react with only one of the cell types to be counted. If only a single label is used, a separate sample is required for each subset to be demonstrated. As a rule, two-color immunofluorescence labeling readily allows visualization of three stained subpopulations (one double positive and two single positives) and one unstained population. Multiplex labeling allows for more economical use of the two-parameter measurement space.

In the simplest form of multiplex labeling, a procedure described by Saunders and Chang<sup>792</sup> and proposed by Mack Fulwyler<sup>793</sup> and, independently, by Tomas Hirschfeld and Myron Block (personal communication, 1981), a mixed cell population is stained with mixtures of antibodies, each of which should, in principle, react with only one cell

subpopulation. Any given antibody present in the mixture may bear one or both of the two labels used, but a unique ratio of labels must be chosen for each antibody present. If phycoerythrin and fluorescein are the two labels chosen, cells reacting with an antibody present only in the phycoerythrin-labeled form will appear along the phycoerythrin fluorescence axis, cells reacting with an antibody present exclusively as the fluorescein conjugate will appear along the fluorescein fluorescence axis, and cells reacting with an antibody present as a 1:1 mixture of fluorescein and phycoerythrin conjugates will appear along a line at 45° to both axes.

A refinement of multiplex staining, described by Horan et al<sup>791</sup>, uses mixtures of fluorescein- and phycoerythrin-labeled and unlabeled antibodies to produce fluorescence intensity differences of several orders of magnitude among the various cell subsets, with data display on a logarithmic scale. Liu et al<sup>1394</sup> demonstrated that helper and suppressor/cytotoxic T cells, NK and B cells, and monocytes could be identified in this fashion in whole blood samples from both normal and HIV-infected individuals, as shown in Figure 7-18.

Multiplex labeling has the potential to fail ungracefully when applied to certain types of samples. For example, small numbers of T cells bearing both CD4 and CD8 antigens may be found in peripheral blood<sup>794</sup>; these might be counted as other cell types. This behavior can, however, be identified by comparisons between multiplex labeled and conventionally labeled samples, allowing the prospective user to determine when the method is and is not suitable. In this context, the results reported with multiplex labeling in HIV-infected samples by Liu et al<sup>1394</sup> were encouraging.

When the previous edition of this book was written, there was a great deal of interest in possible applications of multiplex immunofluorescence to analyses of cells. Most laboratories had only two- or three-color fluorescence measurement capability, and multiplex analysis would have provided them the only means for investigating many phenomena then (and, in many cases, now) of great interest. For example, it was felt that determining the state of activation of various cell subpopulations in HIV-infected patients might provide indicators of both clinical course and response to therapy. Semiquantitative or quantitative analysis of activation antigens such as CD25 and CD71 (the IL-2 and transferrin receptors), and/or of parameters such as RNA content, were known to provide reliable evidence of lymphocyte activation<sup>597-606</sup>.

If conventional staining procedures were used, it would be necessary to use two antibodies, and, therefore, two fluorescence channels, simply to define a single subpopulation of interest. The analysis of an activation antigen or RNA in this population would require a third antibody, or a dye such as pyronin Y, and a third fluorescence channel. In a 3-color instrument, analysis of activation in T-helper and suppressor/cytotoxic cells, B cells, and NK cells would require three tubes using conventional staining. If multiplex staining were used, a cocktail of antibodies labeled with fluorescein and

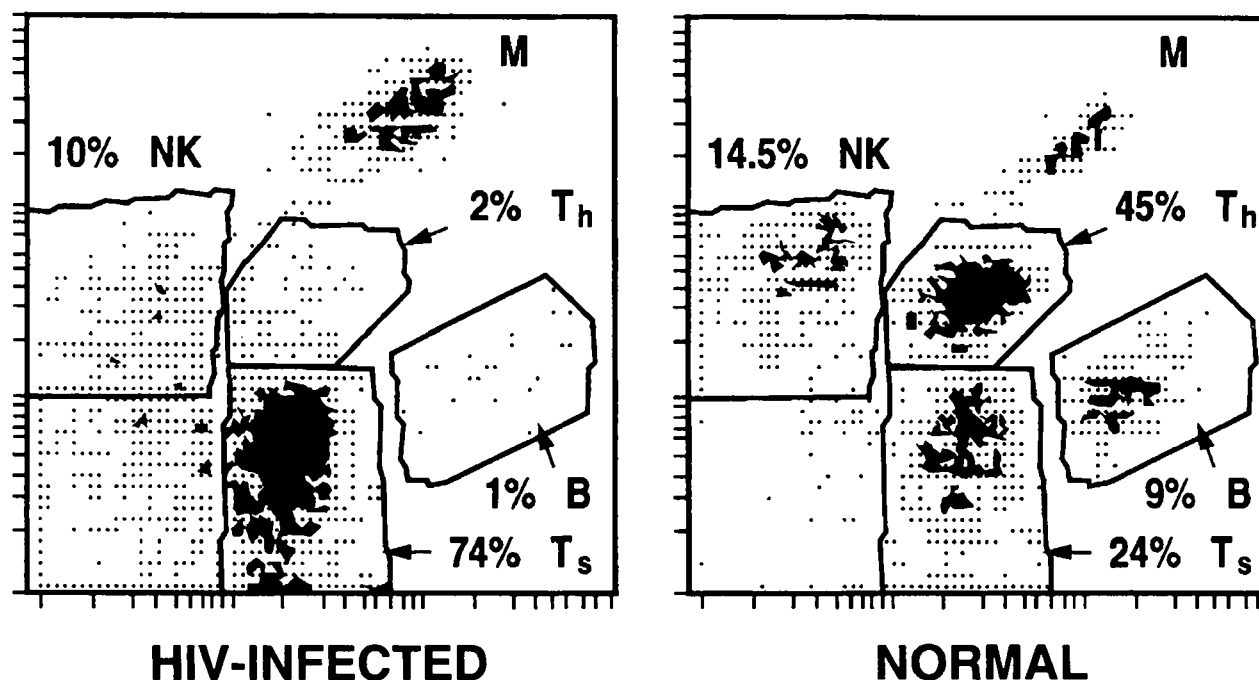

Figure 7-18. Multiplex immunofluorescent labeling to demonstrate helper ( $T_h$ ) and suppressor/cytotoxic ( $T_s$ ) T cells, B cells, NK cells, and monocytes (M) in peripheral blood from an HIV-infected and a normal individual<sup>1394</sup>. Erythrocytes were lysed after dextran sedimentation, and  $2 \times 10^6$  washed leukocytes were stained with a cocktail containing anti-CD3 (T cells; B-D Leu-4: 10  $\mu$ l unconjugated, 10  $\mu$ l FITC-Ab), anti-CD4 ( $T_h$ ; B-D Leu-3a: 20  $\mu$ l PE-Ab), anti-CD8 ( $T_s$ ; B-D Leu-2a: 19  $\mu$ l unconjugated, 1  $\mu$ l PE-Ab), anti-CD14 (monocytes; B-D Leu-M3: 20  $\mu$ l FITC-Ab; Coulter My4: 5  $\mu$ l PE-Ab), anti-CD16 (NK cells; B-D Leu-11c: 20  $\mu$ l PE-Ab) anti-CD19 (B cells; Coulter B1: 5  $\mu$ l FITC-Ab), and anti-CD20 (B cells; B-D Leu-12: 5  $\mu$ l PE-Ab) antibodies at 4 C for 30 min. Cells were washed three times and fixed in 1.5% paraformaldehyde before analysis. Five leukocyte subclasses can be identified and counted in the two-dimensional measurement space. The figure was provided by Alan Landay of Rush-Presbyterian-St.Luke's Medical Center.

PE-Cy5 could be used to identify all four subclasses in one tube, with a third, spectrally distinct marker, e.g., PE-anti-CD25 or -CD71 or pyronin Y serving to define the activation state of all of the subclasses.

The multiplex labeling approach could be, and was, extended to analyses using cocktails containing more than two labels; Carayon, Bord, and Raymond did this to identify eight leukocyte subsets in a single tube<sup>1395</sup>. Buican and Purcell<sup>329</sup> reported that, by application of mathematical techniques similar to those used in computerized tomography, distributions of multiple antibody labeling could be uniquely reconstructed from two-color fluorescence analyses. Buican and Hoffmann<sup>795</sup> also explored the use of two-color measurements to identify multiple subpopulations based on analysis of multiple samples with different labeling ratios, and described apparatus for automated preparation of the required samples<sup>796</sup>. Multiplex labeling was also discussed by Wood<sup>1196</sup>, Mansour et al.<sup>1397,1401</sup>, van Putten et al.<sup>1398,9</sup>, and Hunter et al.<sup>1400</sup>.

In a non-flow application, Ried et al.<sup>1402</sup> used a 3-color multiplex fluorescence method to identify seven different DNA probes bound to chromosomes by digital imaging microscopy. However, a principal obstacle to the use of mul-

tiplex labeling with nucleic acid probes in flow cytometry lies in the low signal intensities expected due to low copy numbers of the nucleic acid sequences sought. Multiplex labeling cannot be expected to work well with very low intensity immunofluorescence signals, either; at levels at which one-color fluorescence is difficult to discriminate from noise, it is even more difficult to attempt to quantify intensity levels of two or more colors.

Where they were feasible, however, it was clear that multiplex labeling methods had great potential for saving time and money. Less sample and possibly less antibody is required, and only a single tube, instead of several, must be analyzed; this results in less preparation time, and in higher sample throughput for both flow cytometers and data analysis systems. However, interest in multiplex analysis of cells has waned as instruments capable of measuring four or more colors replaced two- and three-color systems in laboratories. Multicolor measurements offer most of the advantages of multiplex measurements; it is entirely feasible, for example, to derive counts of CD4+ and CD8+ T lymphocytes from a single tube of lysed whole blood using a mixture of anti-CD45, anti-CD3, anti-CD4, and anti-CD8 antibodies (see Figure 1-17, p.34), and this procedure, like a multiplex

staining procedure, uses relatively little reagent and sample, and requires relatively little analysis time.

What has kept interest in multiplex fluorescence measurement very much alive and well since the previous edition appeared is the application of the technique to chemical analyses of ligands bound to beads<sup>2370-5,2682</sup>, this subject was introduced on p. 48, and will be discussed further in Chapters 8 and 10.

### Cocktail Staining Helps Identify Rare Cells

Cocktail staining has proven useful for the identification of rare cells. Stained cells representing less than 0.1 percent of a population are almost impossible to discriminate from unstained cells on a single-parameter histogram or on a dot plot of fluorescence versus an indifferent parameter such as forward scatter. However, if most or all of the unwanted cells are labeled with a contrasting color, using a cocktail of antibodies, it becomes much easier to find very small subpopulations. This approach was used by Ryan et al<sup>883,1010</sup> for detection of small numbers of leukemic cells following therapy; cocktail staining was also used by Gross et al<sup>1150,2331</sup> to identify cells present at frequencies as low as 1:10,000,000.

### Immunofluorescence Staining Procedures

Due to limitations on reagent specificity and to what was available in the way of labels, earlier immunofluorescence staining methods had to incorporate multiple staining and washing steps, which were time-consuming and labor-intensive. Staining was done either in the cold (4 °C) or with an inhibitor such as sodium azide added to the cells to prevent **capping** or **stripping** of antibody. Even today, when one is using conventional antisera and/or indirect labeling, washing is necessary to prevent unacceptable levels of non-specific background fluorescence, and the low temperature and/or inhibitor become necessary because of the length of time required. With directly labeled antibodies, things get about as easy as they can get; you throw all the antibodies in at once.

It has been argued<sup>175,176</sup> (also R. Hoffman, personal communication) that, when one uses directly labeled monoclonal antibodies, most or all of the wash steps can be omitted with few deleterious effects on results. Hoffman and Hansen<sup>176</sup> described a method for T cell subset analysis in which 50 µl of whole blood were incubated with 100 ng of monoclonal antibody for 10 minutes at room temperature, following which 2 ml of a lysing reagent (8.29 g NH<sub>4</sub>Cl, 37 mg disodium EDTA, and 1 g KHCO<sub>3</sub> per liter, pH 7.3-7.5) was added. Samples were introduced into the flow cytometer within 10 minutes after the lysing reagent was added; immunofluorescence measurements were gated using a combination of forward and side scatter measurements so that, in theory, only lymphocytes were analyzed. This basic methodology, which worked as well with multiple antibodies as with a single antibody, was widely adopted.

Hoffman and his colleagues, then at Ortho, also worked out some quick staining procedures for using **biotin-avidin**

reagents almost as if they were direct labels; since the affinity of avidin for biotin is so high, if you know the amount of biotin-antibody in your staining mixture, you can figure out how much labeled avidin to add so as to end up with slight antibody excess.

Hoffman et al also described a technique<sup>645</sup> for immunofluorescence analysis of leukocytes in whole blood without lysis; a bright fluorescent counterstain, which stains leukocyte nuclei and/or cytoplasm but not erythrocytes, is used to detect and classify leukocytes as well as to gate the fluorescence measurements; Terstappen and Loken<sup>1154</sup> also described triggering on the fluorescence of nuclear stains for analysis in unlysed blood. I used the same trick when I used Hoechst dye staining of nuclei to gate immunofluorescence measurements, but I usually didn't go out of my way to work with unlysed whole blood, since, at one leukocyte per 1,000 erythrocytes, you have to run for several minutes to get immunofluorescence signals from a few thousand leukocytes. If you're willing to accept the longer analysis time, you can even trigger on immunofluorescence signals, which facilitates doing things like just looking at the T cells and ignoring everything else in the sample.

In my view there are few excuses for not using the simpler immunofluorescent staining methods whenever possible, especially since there never seem to be enough hands available to stain all the samples you want to stain. There are, however, situations in which fast, no-wash immunofluorescent staining methods don't work so well, e.g., in the case when the number of antigenic sites per cell is extremely low. Hoffman and Kuhlmann<sup>2482</sup> found that unbound fluorescein- and PE-labeled antibodies, respectively, contributed 4,000 and 1,600 MESF of background fluorescence to the signal in no-wash immunofluorescence analysis, meaning that, if you are set on detecting a few hundred molecules of cell- or bead-bound antibody, you need to wash your cells, and you may need to resort to one or another of the amplification techniques discussed on pp. 343-5.

The simplest amplification technique is, of course, **indirect staining**; Parks et al<sup>674</sup> have discussed alternative methods of indirect staining and their advantages and disadvantages. The most commonly used indirect staining technique uses a fluorescent polyvalent or monoclonal **second antibody** specific for the immunoglobulin type of the primary antibody. After cells are exposed to the primary antibody and washed, they are incubated with the second antibody and washed again before being analyzed. Polyvalent antisera contain antibodies reactive with multiple sites on the primary antibody, and therefore can provide greater amplification than can monoclonal second antibodies; however, unless polyvalent sera are subjected to adsorption and/or affinity chromatography to enrich their content of anti-immunoglobulin antibodies, they are apt to produce high background fluorescence due to binding of labeled irrelevant antibodies to cells not bearing any primary antibody. Monoclonal second antibodies should not produce high background fluorescence; it should therefore be possible, albeit

expensive, to use a mixture of monoclonal antibodies reactive with different sites on the primary antibody to achieve the amplification factor associated with polyclonal antisera and avoid the background fluorescence. I'm not sure whether or not anybody actually does this.

**Protein A**, which is produced by bacteria of the genus *Staphylococcus*, binds strongly to some IgG antibodies and, when fluorescently labeled, can be used as a second reagent for indirect staining. The principal disadvantage of using protein A results from its lack of reactivity with some primary antibodies and its predictable reactivity with host immunoglobulin already bound to cells.

Use of a **biotin-avidin** reaction<sup>300</sup>, in which fluorescently labeled avidin or streptavidin is reacted with biotinylated primary antibody, typically produces brighter staining than would be obtained if the fluorochrome were directly bound to the antibody; this is especially likely to be the case when the fluorochrome is a large molecule such as a phycobiliprotein.

The combination of **hapten-conjugated antibodies** and **fluorescently labeled anti-hapten antibodies**<sup>301</sup> for indirect staining offers advantages in that this approach provides one of the more straightforward ways of indirectly labeling two or more antigens. For example, one could use primary antibodies conjugated with arsanilate and trinitrophenyl radicals, and fluorescein-anti-arsanilate and phycoerythrin-anti-trinitrophenyl secondary antibodies, to obtain amplified signals while minimizing interference between the two staining systems.

Putting antibodies and labels together seems to hold the same fascination for some of us as does playing with Legos and Erector Sets. Along this line, Wognum et al<sup>789</sup> described labeling cells with phycobiliproteins using a tetrameric complex of a mouse monoclonal antibody to a cell surface antigen and a mouse monoclonal antibody to a phycobiliprotein cross-linked with two molecules of a rat monoclonal antibody to mouse immunoglobulin.

### Automated Sample Preparation

Several manufacturers offer devices for rapid lysis, fixation, and immunofluorescent staining of whole blood. You add the blood and antibodies; it does the rest, and, minutes later, you run the sample. Automation has been welcomed, especially by clinical users; more versatile preparation apparatus to meet the more varied needs of the research community is at an earlier evolutionary stage.

### Fluorescence Measurements: Lurching Toward Quantitation

#### Calibration and Controls: Round One

Calibration and control procedures for immunofluorescence or ligand binding work differ substantially from those used for an application such as DNA analysis. In DNA analysis, the cells are typically brightly stained, and one calibrates the apparatus with beads and/or (preferably and) nu-

clei stained with the DNA stain being used, with precision being the primary concern and linearity next on the list. In measurements of weaker fluorescence, the small number of photons coming from stained cells may itself be the limit to precision; the emphasis is on **sensitivity and specificity**. We have to have some idea of how many fluorescent molecules we are detecting and of how much of the fluorescence is due to label specifically bound to the cells of interest.

I have already made the point that most of the argon ion laser source flow cytometers now in use have enough radiometric sensitivity to detect fewer than 1,000 molecules of antibody-bound fluorescein, and that the practical limit of sensitivity is set by the autofluorescence background. Instrumental approaches to discriminating fluorescein immunofluorescence or ligand fluorescence from autofluorescence were discussed on p. 342; in most cases, however, we don't have to carry things quite so far, because we can control for both autofluorescence and nonspecific fluorescence in properly designed **negative control samples**. These, ideally, should be cells that are known not to bear the antigen or ligand-binding entity being measured, to which labeled antibody or ligand has been added.

**Isotype controls**, containing cells and a labeled "irrelevant" antibody of the same isotype class as the reagent, were once almost universally used, and are still widely used; although some have deemed them unnecessary for many common clinical measurements<sup>2683</sup>, others have not<sup>2684</sup>. If you are trying to do quantitative measurements, it's a good idea to have isotype controls, especially if the antigen you are looking for is not present in abundance. When an indirect staining procedure is employed, negative controls should also include samples in which the labeled second reagent is added to cells in the absence of primary antibody.

The ideal **positive control** is composed of cells that are known to bear approximately the same amount of antigen as the cells being analyzed; the objective in instrument setup is to use negative and positive controls to keep both negative and positive cells on scale. This is rarely a problem when you use log amplifiers, but it can be tricky when you're working on a linear scale. Through the years, people have come up with a number of nonfluorescent and not-very-fluorescent test objects to make this stage of the game easier. To answer an old and common question, in this instance, at least, the chicken came first.

**Glutaraldehyde-fixed chicken erythrocytes** become weakly fluorescent due to the presence of compounds formed by the aldehyde binding to amino groups in proteins, and were used since the early 1970's as controls approximating the fluorescence intensity of cells stained with fluorescent antibodies. **Osmium tetroxide-fixed cells**, which are essentially nonfluorescent, have been used to demonstrate spurious fluorescence signals due to fluorescence induced in color glass filters by scattered light.

As hard as it may be for some of you "younger" readers to believe, back in the 1970's, cell sorter operators in many prestigious immunology labs didn't bother with bead con-

trols at all. By the mid-1980's, Coulter, Flow Cytometry Standards Corp., and Polysciences sold lightly labeled fluorescent beads with fluorescence in the same range as that of antibody-stained cells. Ortho distributed Fluorotrol, a mixture of fixed unstained thymocytes and thymocytes covalently labeled at two different intensities with fluorescein; Coulter supplied a preparation of fluorescent fixed cells under the name ImmunoSure. Flow Cytometry Standards and Ortho gave estimates of the number of fluorescein molecules bound to their materials. Caldwell et al<sup>700</sup> proposed the use of cellular fluorescence intensity itself as a quality control parameter in clinical flow cytometry, describing procedures for utilizing the relatively constant stainability of normal human peripheral lymphocytes to control for alterations in reagents as well as for instrumental sources of variability. However, while microscope photometry<sup>1497</sup> demonstrated consistency and reproducibility in fluorescence measurements of beads from Coulter, Covalent Technology, and Polysciences, these beads incorporated dyes other than fluorescein, and therefore could not readily be used to standardize measurements of fluorescein immunofluorescence.

In the late 1980's and 1990's, manufacturers shifted toward the production of controls bearing known amounts of common antibody labels, or known numbers of antibody binding sites, attempting to simplify the process of quantifying flow cytometric measurements of ligand binding or immunofluorescence. These materials were evaluated by relatively large groups of investigators in the United States, Canada, and Europe, and a series of meetings held in 1997 and 1998 brought most of the interested parties together and generated a special issue of *Cytometry*<sup>2379</sup> in which progress was summarized and critical issues were addressed.

### Quantitative Fluorescence Cytometry: Definitions

Henderson et al<sup>2685</sup> defined **quantitative fluorescence cytometry (QFCM)** as "the calibrated measurement of fluorescence intensity from labeled particles...so as to determine the actual number of fluorescent ligands...labeling each particle." A cytometer measures **fluorescence intensity (FI)** of particles, but the measurements are initially reported as unitless histogram channel numbers. **Relative fluorescence intensities (RFIs)** express the relationship between the FIs of two measured particles; they can also be used to convert from histogram channel numbers on a logarithmic scale to linear units. The objective of QFCM as applied to immunofluorescence is determining **antibody-binding capacity (ABC)**, i.e., "the number of antibody molecules bound by a particle when specific binding sites are saturated." To convert from **MESF (Molecules of Equivalent Soluble Fluorochrome) Units** (see pp. 216-7) to ABC, it is necessary to know the labeled antibody's **effective fluorescence/protein ratio,  $F/P_{eff}$** , where  $F/P_{eff}$  is defined as "the average number of MESF per functional ligand molecule in a fluorochrome-ligand conjugate."  $F/P_{eff}$  is analogous to, but more precise than, the older fluorochrome/protein, or  $F/P$ , ratio.

Schwartz et al<sup>2686</sup> established a taxonomy of **fluorescence standards** used for flow cytometry. A **Type 0 standard**, or **certified blank**, is a particle approximately the size of a cell (a lymphocyte is the typical cell in most discussions of QFCM). Certified blanks have a single, very low fluorescence intensity. **Type I standards** are better known as **alignment particles**; they are typically highly labeled and highly uniform in size, producing a very bright fluorescence signal with a low CV. Type Ia standards are smaller than cells (think of the 1-2  $\mu\text{m}$  beads typically used to align an instrument and check its precision); Type Ib standards are cell-sized.

**Type II standards**, or **reference particles**, are the size of cells, and yield bright fluorescence signals; they need not be uniform in size. Type IIA particles are not spectrally matched to fluorochromes in the sample, and their fluorescence is not environmentally sensitive; Type IIB particles are environmentally sensitive and spectrally matched. Type IIC particles are not themselves labeled, but bind a relatively large amount of labeled antibody, obviously thereby sharing its spectrum and environmental sensitivity.

**Type III standards**, or **calibration particles**, are cell-sized, and not necessarily uniform in size. They come in sets including particles with several fluorescence intensity levels, ranging from dim to bright. Type IIIA, IIIB, and IIIC standards, respectively, share the properties of Type IIA, IIB, and IIC standards in terms of labeling, spectra and environmental sensitivity, and antibody binding. Type IIIC standards may be used to determine appropriate settings for **fluorescence compensation**; since they provide a known, wide range of fluorescence intensities using the same antibodies as are used to stain cell samples, they may be superior to single antibody-stained cell samples for this purpose.

### Calibration Particles for QFCM

Successful quantitative fluorescence cytometry requires a well-aligned instrument; there has been some discussion of measurements of instrument performance on pp. 214-7, and additional coverage will be found in Chapter 10. I will deal here with the particles and methods needed to do QFCM with an apparatus in good working order.

"**Quantum Beads**" bearing known numbers of **Molecule Equivalents of Soluble Fluorochrome (MESF)** of fluorescein and phycoerythrin are Type IIIB standards. They were developed and produced by Flow Cytometry Standards Corporation<sup>1161</sup>, which also developed **Quantum Simply Cellular<sup>®</sup> (QSC)** beads, Type IIIC standards capable of binding known numbers of antibody molecules (see pp. 48-9 and 199-201). The surface of a QSC bead is coated with a mixture of polyclonal goat antibodies to the Fc portions of various mouse Ig subtypes; the mechanism of binding of mouse monoclonal antibodies (MoAbs) to QSC beads is therefore quite unlike the mechanism by which the monoclonal antibodies bind to their targets. Fluorescent MoAbs may need to be incubated with QSC beads for a week or more in order for the fluorescence intensity of the beads to

reach a plateau; the beads can then be used for some time thereafter<sup>2687</sup>. QSC beads, used with directly labeled antibodies, provide a standard curve spanning a range from fewer than 10,000 to over 100,000 molecules of bound antibody, allowing direct comparison with labeled cells (Figure 1-20, p. 49). Both Quantum Beads (PE-Cy5- and APC-labeled beads are now offered in addition to the fluorescein- and PE-labeled products) and Quantum Simply Cellular Beads (now available to bind human antibodies as well as mouse antibodies) may be purchased from **Bangs Laboratories**.

In 1985, Poncelet and Carayon<sup>1488</sup> developed a method they called **quantitative indirect immunofluorescence assay (QIFI)** to determine the absolute number of antibody binding sites on lymphoid cells by indirect immunofluorescence flow cytometry after saturation with monoclonal antibody, when binding is likely to be monovalent. The p67 T cell-associated antigen was quantified on cell lines by the binding of radiolabeled antibody. Then, saturating doses of unlabeled antibody followed by fluorescent anti-mouse antibody were applied to the cell lines to build a standard curve relating the mean fluorescence intensity of cells to the mean number of cell-bound primary antibody molecules. This curve (a straight line) was used to assess the absolute number of antibody molecules bound to other lymphoid cells. The technique was shown to be applicable to other IgG antibodies even when they were used in unpurified form.

The QIFI assay as originally described required the use of cell lines and radiolabeled antibodies to establish a standard curve; this limited its appeal, although, as Dux et al<sup>1489</sup> reported, the method allowed quantitative analysis even of antigens expressed at low densities. Poncelet et al<sup>1490,1493</sup> subsequently developed beads, now available as the **QIFIKIT™** (Biotex, Marseille, France; available from **DakoCytomation**), which can be used as secondary standards, making quantitative indirect immunofluorescence assay generally accessible. The QIFIKIT beads are Type IIIC standards, containing known numbers of mouse monoclonal antibodies bound to an antigen (CD5) on the bead surface. A labeled secondary antibody therefore binds to a QIFIKIT bead by the same mechanism as if it were binding to a mouse monoclonal antibody in or on a cell. Using the QIFI methodology, Poncelet et al<sup>1491</sup> examined normal human lymphocytes, and found that expression of CD4 and CD45 antigens was relatively stable, at  $48,000 \pm 6,000$  and  $180,000 \pm 17,000$  binding sites/cell, respectively, while other antigens were more variable. In HIV-infected individuals, CD4 expression remained at 46,000 sites/cell, even with disease progression<sup>1492</sup>. Bikoue et al<sup>2688</sup>, using QIFI technology, reported finding a mean CD4 expression level of 47,000 sites/cell on CD4+ lymphocytes.

**BD Biosciences**, which was just B-D at the time, took a serious plunge into quantitative immunofluorescence in the mid-1990's, developing the **QuantiBRITE** family of phycoerythrin-labeled beads and antibodies.<sup>2481,2,2689</sup> QuantiBRITE beads are Type IIIB particles with four intensity levels of phycoerythrin labeling, ranging from approximately 1,500

PE molecules/bead to approximately 130,000 PE molecules/bead. QuantiBRITE kits include one antibody that is a 1:1 PE:IgG conjugate; antibodies to CD20, CD38, CD64, and HLA-DR are available, as well as custom 1:1 PE conjugates. Using the QuantiBRITE system, Davis et al<sup>2481</sup> reported the mean level of expression of CD4 on CD4+ lymphocytes to be 49,000 binding sites/cell; they found binding of their (B-D's) monoclonal antibody to be bivalent, indicating that there should be approximately 98,000 CD4 binding epitopes on the cell surface. Pannu et al, also at B-D, found a mean of 51,000 CD4 sites/CD4+ lymphocyte<sup>2482</sup>.

Although it does not seem to be in the current catalogue, B-D made a 1:1 PE:CD4 antibody that was used in the CD4 studies they did and also in several studies of CD38 levels on CD8+ T cells in patients with HIV infection. Janis Giorgi had noted that elevated RFI of CD38 expression was an indicator of poor prognosis in HIV infection<sup>2693</sup>, and initially developed a method for quantitation of cell surface CD38 on CD8+ T cells using the fluorescence intensity of CD4 on CD4+ T cells as a standard<sup>2691</sup>. While an initial study by Iyer et al<sup>2689</sup> found that measured CD38 fluorescence intensity values obtained using QuantiBRITE beads as intensity standards were essentially the same as those obtained using CD4 as a standard, a later multicenter study<sup>2692</sup> detected small but significant differences, and recommended that laboratories consistently use one standard or the other.

I will generalize from this; while, in principle, it would be desirable for flow cytometry labs everywhere to get the same numbers from the same samples, experience with quality assurance surveys over the years tells us that a great deal of effort is required simply to insure that critical clinical data such as CD4+ T cell counts remain reliable from lab to lab. Quantitative fluorescence measurements, and immunofluorescence measurements in particular, present more of a challenge. Recall that, while cellular DNA content can be measured with very high precision, the agreed upon definition of DNA aneuploidy is not based on a numerical value for DNA content, but, instead, on the DNA index, i.e., the ratio of DNA contents in tumor and stromal cells in the same sample (p. 317). DNA content measurement is based on analyses of strong signals, measured on linear scales, with minimal contributions to variance from photoelectron statistics, and the biological variance of DNA content, at least in  $G_0/G_1$  phase stromal cells, is extremely small. Fluorescence compensation is not, as a general rule, used for DNA content measurement.

Immunofluorescence measurement is based on analyses of relatively weak signals, with fluorescence intensities typically no more than 1/100 of those typically encountered in DNA content measurement. Measurements are almost always made on logarithmic scales, and often represent the outputs of logarithmic amplifiers, which are likely to deviate substantially from true logarithmic response. Photoelectron statistics may contribute substantially to measurement variance, particularly at low signal levels, and the biological variance of the amounts of most antigens in or on most cell

types is relatively large. Fluorescence compensation is likely to be applied to measurements used for quantitative immunofluorescence flow cytometry, and may, particularly if done in hardware, introduce significant inaccuracy into results. All of this makes it unlikely that a large number of labs will be able to get fluorescence intensity measurements that agree within one or two percent.

It is not unlikely, however, that we will be able to get agreement within ten percent, or even five percent, and that may be good enough. I mentioned above that Quantum Simply Cellular Beads incorporate antibodies to several classes of mouse immunoglobulins; they are therefore unlikely to have exactly the same number of binding sites for antibodies of each class, and might also bind differently to antibodies bearing different labels. This could make it possible to get different values for numbers of binding sites per cell when the beads are used with different antibodies to the same cell surface antigen, although the results would remain consistent for individual antibodies. However, as can be seen from Figure 7-19, the number of CD4 epitopes on CD4+ T lymphocytes determined using antibody-binding beads (R. Vogt, personal communication), about 47,000 sites/cell, is very close to those reported by Poncelet et al<sup>1491-2</sup> and Bikoue et al<sup>12688</sup> using the QIFI method, and by others using QuantiBRITE beads<sup>2481-2</sup>.

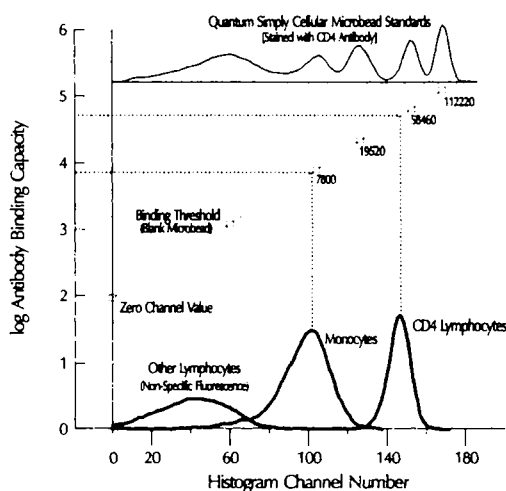

Figure 7-19. Quantitative determination of CD4 epitopes on peripheral blood lymphocytes and monocytes using QSC antibody-binding beads as intensity standards (provided by Robert Vogt, Centers for Disease Control).

In 1989 and 1991, Vogt et al<sup>1505-6</sup> examined intra- and interlaboratory variation in quantitative fluorescence measurement using both fluorescein-labeled beads and Fluorotrol as standards; while reproducibility was very good in a single laboratory, a study of 43 cytometers in 34 laboratories showed CVs in the 20-30% range for measurements of CD4 intensity of lymphocytes, although CVs dropped to 11% when a corrective factor based on Fluorotrol intensity values

was applied. Those early results were encouraging. However, Lenkei et al<sup>2693</sup> reported in 1998 that ABCs determined using three different instruments in one laboratory, with different calibrators and with different fluorochrome conjugates of monoclonal antibodies, varied by 20-40 percent. Serke et al<sup>2687</sup>, while noting that ABCs determined using the QIFIKIT and QuantiBRITE beads were similar, found large differences in titration curves between cells and QSC beads for a large number of MoAbs to different CD antigens, and differences in binding of fluorescein- and PE-labeled conjugates of the same MoAb to QSC beads. It is likely that the behavior reported for QSC beads relates to the fact that these beads bind antibodies via the Fc portion, while relevant cellular antigens bind the variable regions of the same antibodies.

### Defining a Window of Analysis

Relating a measurement channel number to ABCs or MESF units requires the definition of a **Window of Analysis**, according to a procedure specified by Schwartz et al<sup>2694</sup>. While Figure 7-19 illustrates the results of such a procedure, assigning ABC values for anti-CD4 antibody to lymphocytes and monocytes based on fluorescence values obtained from QSC beads to which the antibody had been bound, I will work from Figure 4-60 (p. 216), which deals in MESF units, because it includes more of the "nuts and bolts."

The first item of business is measurement of a Type IIIB or IIIC standard; the former will give a scale calibrated in MESF units, and the latter a scale calibrated in ABCs. The Type IIIB standard used in Figure 4-60 was a set of Quantum beads labeled with fluorescein. The values we need are the histogram channel numbers for the peaks representing the four labeled beads and the blank bead in the bead kit. In this instance, measurements were recorded on a 256-channel (8-bit) logarithmic scale; Schwartz et al recommend converting measurements on higher resolution scales to a 256-channel scale, for reasons that will shortly become apparent.

Working with the known values for MESF units (or ABCs) assigned to the labeled beads by the vendor, we perform a linear regression analysis to get an equation of the form:

$$[\text{channel \#}] = a [\log \text{MESF}] + b.$$

In the example shown in Figure 4-60, I happen to have used the log of [MESF/100] which is [log MESF] - 2, so the right regression equation is actually:

$$[\text{channel \#}] = 43 \log \text{MESF} - 101,$$

rather than the equation shown at the top of the figure.

The slope, *a*, of the regression line defines the **coefficient of response**, indicating, at least in theory, the number of decades of dynamic range available in the measurement. If the 256-channel scale includes exactly four decades, the value of *a* should be 64 (i.e., 256/4); if it is a three-decade scale, *a* should be 85.33 (i.e., 256/3). Note that the value of *a* associated with Figure 4-60 is 43; this suggests that the

measurement scale encompasses 5.9 decades. Don't believe it. What it actually indicates is that the maximum voltage output from the log amp used to process the signals was less than the full-scale input voltage of the analog-to-digital converter used to collect the data. That happened in my home-built Cytomutt; you are unlikely to have the same problem in your instrument, and, if you have what is nominally a four-decade logarithmic scale and end up with a value of  $a$  that is less than 59 or more than 69 (these values correspond to 4.3 and 3.7 decade ranges), you should probably have your system looked at. In case you haven't already guessed, we convert everything to a 256-channel scale so we can always use 64 as the ideal value of  $a$  for a four-decade logarithmic scale and 85.33 as the ideal value for a three-decade scale.

The points representing the measured values of the beads are pretty close to the regression line in both Figure 7-19 and Figure 4-60. Part of that is due to the fact that we are working on a semi-log scale; the deviations would be larger on a linear scale. However, we really can't rely on our eyeballs to give us a robust measure of how close our measured points are to the calculated line. The regression line is calculated using the method of least squares, meaning that the chosen line minimizes the sum of the squares of the differences between observed and calculated values of channel numbers. While I am on the subject of the regression line, I should point out something else that might otherwise confuse you.

Under most circumstances, we plot the value of a dependent variable in the vertical (Y) direction, and the value of an independent variable in the horizontal (X) direction, and calculate a regression equation:  $Y = aX + b$ . In the game we're playing here, we have the dependent variable, channel number, plotted on the X axis, and the independent variable, MESF units (or ABCs) plotted on the Y axis, so our regression equation is really:  $X = aY + b$ . Just so you know.

In order to determine the extent to which our logarithmic scale deviates from ideal response, we go back to our regression equation, and, taking the actual channel numbers we used to derive it, work backwards to calculate the MESF values that would fall on the line. For example, in Figure 4-60, the data point representing the bead with 70,000 MESF is at channel 108. The equation tells us that

$$108 = 43 \log [\text{MESF}] - 101,$$

so  $\log [\text{MESF}] = (209/43)$ , or 4.860, and the value of MESF that would fall on the line at channel 108 is  $10^{4.860}$ , or 72,521 MESF.

Having calculated all of the MESF (or ABC) values as just described, we find the percentage differences between them and the known MESF (or ABC) values supplied by the bead vendor. For example,  $72,521/70,000 = 1.036$ ; the known data value therefore deviates from the value calculated to lie on the regression line by 3.6 percent. Our quality measure is the **average residual percent**, which we get by doing the calculations for all the data points corresponding

to known MESF or ABC values (we leave the blank out), adding them up, and dividing by the number of data points. The average residual percent should be less than 3 for MESF and less than 5 for ABCs; the line in Figure 4.60, which looks so close to the data points, actually has an unacceptably high value.

Getting back to the window of analysis, we next obtain the MESF numbers corresponding to channels 0 and 255, in the same fashion as we calculated values on the line to get the average residual percentage. For the data in Figure 4-60, the **zero channel value (ZCV)** is 223 MESF; the **maximum channel value** would be 190,138,370 MESF, but, as I noted a few paragraphs back, that's not a believable value because of a peculiarity of the electronics. The **window of analysis** runs from the zero channel value to the maximum channel value; it is generally suggested that instrument gain settings be adjusted to make the window of analysis run from 100-300 MESF or ABC (an acceptable range for ZCV) to 1,000,000-3,000,000 MESF or ABC.

Note that if the MESF or ABC value for the blank bead is higher than the ZCV, which it will be if some or all of the blank beads appear on scale, the instrument cannot actually detect a signal at the level of the ZCV. It used to be commonplace to define the **detection threshold** as the median value of the peak representing blank beads or unstained cells; it is advisable to use the median rather than the mean because low values tend to pile up in channel 0, which would skew the value of the mean, but not the value of the median. It makes more sense to define a threshold value to include no more than the upper few percent of events in the blank peak; that this number should be no higher than 1000 MESF or ABC, and, if it is that high, the bottom decade of the four-decade range (from 100 to 999 MESF/ABC) is essentially totally occupied by noise, making measurement values in this range meaningless.

The bottom line is that you can't expect to get accurate quantitation of values in peaks that overlap substantially with the blank; that concludes this discussion, which has gotten long enough so that it might be called "Window of Analysis Restaurant." You can get the programs to do the calculations just described from the instrument manufacturers and from third parties (see Software Sources in Chapter 11); just remember that you can't get anything you want from QFCM.

### Type IIIA versus Type IIIB and IIIC Standards

While Type IIIB and IIIC standard beads provide accurate calibration of a cytometer's fluorescence intensity scale, and are spectrally matched to the labels used for QFCM, these types of beads, and particularly those bearing phyco-biliproteins or antibodies, are somewhat less stable than Type IIIA beads. Type IIIA beads, which are hard-dyed, emit fluorescence in one or more of the same spectral regions in which common labels emit, but are not spectrally matched to the labels and are not environmentally sensitive. The relative fluorescence intensities of a Type IIIA and a

Type IIIB or IIIC bead may be influenced by the excitation wavelength and power used, and the detector bandwidth and sensitivity.

However, once a Type IIIB or Type IIIC bead has been used to establish a window of analysis, running a sample of Type IIIA beads with appropriate emission characteristics, using the same instrument gain settings, can provide a "Rosetta Stone" that will allow conversion between fluorescence values obtained from the Type IIIA beads and MESF or ABC values. As long as no significant changes are made in instrument configuration, setting up the instrument by adjusting gains to keep the Type IIIA beads at or very near the same channels in which they appeared in the original run will restore the window of analysis. Type IIIA beads are available from **Beckman Coulter**, **DakoCytomation**, **Molecular Probes**, **Polysciences**, and **Spherotech**.

### Other Aspects of Fluorescence Quantitation

#### What is "Positive"? What is "Negative"?

Some of the harder-to-answer questions in analysis of immunofluorescence and ligand binding relate to how one defines **what is "negative" and what is "positive,"** this could be considered to be quantitation at the 1-bit level. Even at this level, there aren't always unequivocal answers. Generally speaking, if the cells in your sample have been taken directly from places in which they acquire or lose a particular antigen, you'll see a **continuous distribution** of immunofluorescence intensities going from some positive value all the way down to zero. This type of distribution is typically observed when cells such as stimulated peripheral blood lymphocytes are stained for activation antigens such as the IL-2 and transferrin receptors (CD25 and CD71, respectively), which emerge following exposure of cells to antigens or mitogens.

People typically consider cells from such continuous immunofluorescence distributions as "positive" for the antigen in question when their fluorescence intensity exceeds that of all but a small (usually 1-5%) fraction of a control population. It is not always clear what constitutes an appropriate control population. When stimulated lymphocytes are analyzed, unstimulated lymphocytes are generally used as a control. However, unstimulated lymphocytes may express low levels of activation antigens, and an unstimulated cell population may contain some cells that were activated before being drawn from the donor, which can be expected to bear the antigen being sought. Things get even more complicated when the antigen in question is one that is expressed on other cell types, such as monocytes, which may contaminate a lymphocyte gate.

When cells acquire or lose an antigen outside the compartment in which they are sampled, it is possible to obtain distributions containing clearly positive and clearly negative cells. T lymphocytes, for example, acquire both CD4 and CD8 antigens in the thymus, and generally lose one or the other before leaving the thymus. Thus, the distributions of

these antigens in T cells from peripheral blood are typically bimodal, with few, if any, cells lying between the positive and negative peaks, while the distributions of the same antigens in thymocytes are continuous<sup>78</sup> (also see Figure 5-11, p. 241).

Chapter 5 devotes a fair amount of space to discussion of mathematical and statistical techniques that attempt to resolve weakly stained from unstained cells. Sladek and Jacobberger<sup>1497</sup> considered the problem of analysis of data from cells expressing low levels of intracellular antigen and, in a comparison of several methods, found mathematical modeling preferable to histogram subtraction (p. 245).

I am of the opinion that is advisable to rephrase unanswerable questions rather than to torture the data to extract the answers you want; when dealing with continuous distributions, it makes more sense to me to get accurate numerical values for medians and quartiles (p. 235-6) than to assign more arbitrary numbers to represent fractions of "positive" and "negative" cells. However, there may be a way of testing mathematical methods that purport to discriminate dim positives from negatives.

#### Making Weakly Fluorescent Beads and Cells: Do This Trick at Home!

The precision with which you can put only a few hundred molecules of a label or antibody on a cell or bead is limited by Poisson statistics (see the discussion of molecular shot noise on p. 341). You can't buy antibody-binding beads with a binding capacity of 100 antibodies. However, you can buy beads with a binding capacity of 5,000 antibodies, and, by incubating them with a 1:49 mixture of labeled and unlabeled antibodies, get an average of 100 labeled antibodies on each bead<sup>2695</sup>. The standard deviation, thanks to Poisson statistics, will, of course, be at least 10, meaning that the CV of the fluorescence distribution can be no lower than 10 percent, but you may not even be able to detect the fluorescence on your flow cytometer, and, if you can, it's a pretty good bet that photoelectron statistics will contribute more than molecular shot noise to the variance. You can play the same game with cells; a CD4+ T cell has about 50,000 binding sites for CD4 antibody, and, if you stain peripheral blood cells with a 1:99 mixture of labeled and unlabeled antibody, you'll get an average of 500 molecules of label on each CD4+ T cell<sup>2:96</sup>.

The stoichiometry described above only applies if the labeled and unlabeled antibody have equal shots at binding to cells. An unlabeled IgG antibody has a molecular weight of about 160,000, and, if you put 3 molecules of fluorescein on it, the molecular weight goes up to about 161,200. The difference in molecular weights between labeled and unlabeled antibody won't affect the binding characteristics much, so the ratio of labeled to unlabeled antibodies on beads, or cells, will be the same as the ratio in solution.

An IgG antibody labeled with 1 molecule of phycoerythrin has a molecular weight of about 400,000, and the much lighter unlabeled antibody will have an advantage in

binding to beads or cells, with the result that the ratio of labeled to unlabeled bead- or cell-bound antibody will be lower than the ratio of labeled to unlabeled antibody in solution. You can fix this, and get nearly the same ratios for bead- or cell-bound antibodies as you start with in solution, by using phycoerythrin that has been bleached by exposure to strong light (an hour or two of sunlight will do) as the “unlabeled” antibody when you work with a phycoerythrin-labeled antibody.

A slight variation on this theme should provide a control for testing various computational methods of discriminating weakly labeled and unlabeled cells. It requires an instrument with 488 nm and red (633 or 635 nm) excitation beams. Stain beads or cells with a near-normal concentration of APC-labeled antibody to which you add a very small amount of fluorescein-labeled antibody. You should then be readily able to discriminate stained and unstained beads or cells on the basis of APC fluorescence, and to titrate the fluorescein fluorescence down so you have difficulty discriminating stained and unstained objects. If the computational method gives you the same numbers you get from gating and counting the APC-stained and unstained beads or cells, it's a winner. You don't need to know the exact stoichiometry of stained and unstained cells here, so it doesn't matter that conjugated APC adds at least 33,000 to the molecular weight of an antibody. You also don't have to worry about energy transfer from the fluorescein to the APC, because you can raise the ratio of fluorescein- and APC-labeled antibodies to get a weak, but detectable fluorescein signal.

### Correlating Cytometry and Biochemistry: Studies of Antibody Binding Chemistry

Binding of antibodies, or any other ligands, to chemical structures on or in cells follows the rules of chemical kinetics and thermodynamics. Most of the antibodies used for cytometry are bivalent, but whether binding to their targets is bivalent, monovalent, or mixed depends on a number of factors, with the affinity or avidity of the antibody and the abundance and availability of the targets all exerting strong influences.

We generally attempt to saturate binding sites when performing immunofluorescent staining procedures, particularly when the objective is quantitative fluorescence measurement. However, Eric Martz pointed out a long time ago (personal communication, 1993) that if antibody and cell concentrations and incubation time are arranged so that binding is limited by the diffusion rate of antibody, rather than by the amount of antibody present in the sample, the fluorescence intensities of cells and beads should remain proportional to the number of binding sites on each, even at subsaturating antibody concentrations. In theory, we should be able to get away with using less antibody. In practice, most people will continue to titrate antibodies, adding more until the cells of interest don't get any brighter, and only take comfort from the theory when they find, as we all do

from time to time, that an antibody straight out of the bottle is too dilute to saturate binding sites.

Flow cytometry can be, and has been, used to determine the binding parameters of antibodies. Bardsley et al<sup>1496</sup> developed a model and computer program for determining association constants of antibodies binding to cell surface antigens, which takes into account variations in antibody concentration as well as variations in antigen expression. Benedict et al<sup>2697</sup> described a flow cytometric assay and its use to determine the binding affinity of an anti-CD34 scFv antibody. Siiman and Burshteyn<sup>2698</sup> used competitive binding to determine binding constants for a variety of labeled and unlabeled MoAbs to cell surface markers, and to enumerate the numbers of target binding sites present on cells. A provocative paper by Lamvik et al<sup>2699</sup> reports that binding of unlabeled secondary antibody may increase binding of primary monoclonal antibodies (labeled in this instance, to allow the determination to be done) to cell surface antigens on fixed, permeabilized cells. Both equilibrium and kinetic measurements (about which more will be said in a later section) have been used in flow cytometric studies of antibody binding<sup>2700</sup>.

Quantitative measurement of cellular constituents using immunofluorescence flow cytometry benefits from comparison and correlation of results obtained using flow cytometry and other analytical techniques. Sarin and Saxena<sup>1590</sup>, for example, established a correlation between flow cytometric measurements of histocompatibility antigens and measurements by ELISA.

### Correlating Cytometry and Biochemistry: Intracellular Antigen Measurements

Establishing correlations between flow cytometry results and results of more classical methods is of particular importance in analysis of intracellular antigens. The usual procedures for analysis of intracellular antigens require fixation and permeabilization of cells, in order to achieve the conflicting ends of allowing molecules as big as labeled antibodies to get into cells and retaining molecular targets which may be smaller in size.

Jacobberger and his colleagues<sup>2701-2</sup> have studied quantitative aspects of antibody binding to cellular constituents, with particular emphasis on intracellular antigens. A comprehensive review<sup>2701</sup> discusses basic chemistry and immunochemistry, fixation and sample preparation, and both equilibrium and kinetic measurement methods for flow cytometric analysis. Another paper<sup>2702</sup> describes correlation of quantitative measurements of SV40 T antigen with quantitative Western blots.

There are at least a few tricks that allow flow cytometry to be used to demonstrate and quantitate intracellular antigens in living cells, allowing cells bearing desired antigens in appropriate amounts to be sorted for culture and further analysis.

Detection of cytokine production by T cells (reviewed by Maino and Picker<sup>2703</sup>) has become a favored means of identi-

ying cells participating in an immune reaction against a defined antigen. The usual procedure involves incubation of cells with the antigen, addition of brefeldin A to prevent cytokines from being secreted, staining of relevant surface antigens, fixation and permeabilization, and staining of intracellular cytokines. An alternative technology developed by Manz et al<sup>2704</sup> creates a **cell-surface affinity matrix** on the cell surface, first biotinylating cell surface proteins, and subsequently attaching streptavidin-tagged anti-cytokine antibodies to the biotin molecules. Cytokine secretion is not inhibited; instead, cytokines are secreted, and captured by the antibodies attached to the cell surface, on which they can be demonstrated following addition of fluorescent-labeled anti-cytokine antibodies. Pittet et al<sup>2705</sup> combined an anti-cytokine cell-surface affinity matrix with tetramer staining (introduced on pp. 47-8); this permits sorting of live, antigen-specific, cytokine-secreting cells.

Berglund and Starkey<sup>1234</sup> used **electroporation** to permit the introduction of labeled anti-oncogene antibodies into cells, at least some of which survived the procedure. Morris et al<sup>2706</sup> may have developed a kinder, gentler method; they made a 21-residue peptide carrier, pep-1, incorporating sequences known to be able to promote transport of proteins across membranes, and succeeded in introducing a number of proteins, including two different fluoresceinated antibodies, into living mammalian cells following the formation of complexes between the proteins and pep-1. The antibodies localized correctly to intracellular actin and to a lysosome-associated membrane protein. It remains to be seen whether carrier peptides can make it possible to do quantitative or semiquantitative immunofluorescence analyses of intracellular antigens in living cells.

### Analyzing Immunofluorescence Data

We now turn our attention to what we can and can't learn from immunofluorescence measurements. Some aspects of this have come up in Chapter 5, others will come up in Chapter 10.

Some quantitative questions may actually be easier to answer than some qualitative ones. Like most histograms obtained from flow cytometry, immunofluorescence histograms typically contain data from 10,000 or more cells, and thus represent huge sample sizes when compared to most of the data sets with which statisticians normally have to contend. As a result, you can pretty much assume that a visible difference between two smoothed histograms is statistically significant; you cannot, however, assume that the significant difference is due to a significant biological difference between the cell populations from which the distributions were obtained, because instrumental variation and differences in reagents and sample preparation can also produce statistically significant differences. Intensity calibration makes histogram comparison easier than it might otherwise be.

If you are trying to demonstrate **differences between populations**, it is often useful to construct "envelopes" in which the area between the high and low values for each

channel, taken from two or three replicates of control and experimental histograms done at different times, is shaded. Gaps between the control and experimental envelopes provide strong support for the hypothesis that control and experimental populations differ. Alternative methods for averaging and comparing histograms have been described by Marti et al<sup>798</sup> and Traill et al<sup>799</sup>.

Mathematical models, while not applied to immunofluorescence to nearly the extent to which they have been used for DNA analysis, had been used by some authors. Takase et al<sup>1494</sup> used nonlinear least squares curve fitting to calculate the mean and standard deviation of immunofluorescence distributions, and Shabtai et al<sup>1495</sup> used a Euclidean distance vector to describe fluorescence intensity changes in two-color measurements.

When the previous edition of this book appeared, there were a few papers in the literature<sup>1501-4</sup> reporting fluorescence intensity measurements in terms of fluorescein MESF units. Others had used simpler, more empirical approaches; Terstappen et al<sup>1498</sup> represented amounts of surface antigens on myeloid cells by their mean fluorescence intensities in comparison with the background fluorescence of each cell type. Christopoulos et al<sup>1499</sup> used the same measure of intensity to quantify platelet-bound immunoglobulin.

### Estimating Antigen or Receptor Surface Density

**Surface density of antigenic or receptor sites** can be estimated by dividing the number of bound ligand molecules by the cell surface area. An approximation to an absolute value for cell surface area can be obtained from an electronic measurement of cell volume by analog or digital computation of the  $2/3$  power of volume<sup>311</sup>. Use of this technique is obviously feasible only with flow cytometers capable of making volume measurements. However, since both cell surface area and the "cell size" measurement obtained from forward light scattering are (allegedly) approximately proportional to the square of cell diameter, the ratio of immunofluorescence and scatter signals can serve acceptably as a parameter representative of antigen surface density for making comparisons.

If we actually know how many antigenic or receptor sites there are on the cell, you might think we should aim for surface density in sites per square micrometer. However, while flow cytometry, with appropriate calibrators, can fairly readily give us cell volumes in femtoliters, we'd have to make some pretty rash assumptions to get a surface area from that. It's acceptable to assume the cell is roughly spherical, and calculate an approximate radius from the volume. In reality, we know that no cell surface is a completely smooth sphere, and that real cell surfaces differ in their degree of apparent roughness, as seen, for example, by scanning electron microscopy; this means that cells of roughly the same size can have substantially different true surface areas. Assuming cells are smooth and spherical so you can report "exact" values of surface antigen density doesn't make much sense.

## Quantitative Fluorescence: Problems and Prospects

Shortly before the publication of the October 1998 *Cytometry* special issue on Quantitative Fluorescence Cytometry<sup>2379</sup>, Nicholson and Stetler-Stevenson opined: "Although quantitative flow cytometry is currently drawing a lot of attention, much of the attention is focused in the wrong area. The greatest value that quantitation has provided to the clinical laboratory has been on focusing attention to properly setting up and calibrating flow cytometers. Being able to consistently perform semiquantitative measurements has the most benefit in most clinical settings." They noted that quantitation of CD38 expression on CD8+ T cells in HIV infection<sup>2689-92</sup> represented the only case in which measurements of antibody binding capacity might be important for clinical management.

I won't argue. I am also of the opinion that paying attention to quantitative aspects of immunofluorescence measurement is at least as important for quality assurance as for any other clinical purpose. However, had quantitative fluorescence cytometry not developed to the level at which it was by 1998, it would not have been possible to establish the clinical relevance of CD38 measurements, and we can only find additional instances in which quantitation may be necessary by making more quantitative measurements.

At the present time, we have more problems than solutions. The number of antibody binding sites on cells is known to be influenced by preparative methods, including lysis and fixation, and we will need to standardize the preparative techniques in order to permit widespread application of any quantitative fluorescence measurement procedure. Antibody affinity and binding valency can exert profound effects on ABC determinations, and antibody labels may influence these characteristics. Ideally, there should be little or no spectral overlap between the antibody label used for quantitative measurements and those used to define the gates in which the cells of interest lie, because spectral crosstalk into the channel used for quantitation will increase the background noise level and reduce measurement sensitivity. The label best established for quantitation is probably phycoerythrin; however, the temptation to attempt to do quantitative measurements using phycoerythrin, with a 488 nm laser also exciting antibodies labeled with fluorescein, PE-Texas red, PE-Cy5, PE-Cy5.5, and PE-Cy7, must be strongly resisted. We can, after all, now use three red-excited labels (APC, APC-Cy5.5, and APC-Cy7) for gating, minimizing interference with quantitative measurements using PE. And we still worry about calibrating the calibrators and standardizing the standards.

As I mentioned on pp. 294-5, there are some heavy hitters on the case. The National Institute of Standards and Technology (NIST) is getting into the business of standardizing fluorescent materials<sup>2582-4</sup>, and will be producing and certifying standard solutions and particles, and an NCCLS (NCCLS used to be the National Committee for Clinical Laboratory Standards; having gone international, it is now

simply NCCLS, usually pronounced "nickels") subcommittee is developing a guideline for Fluorescence Calibration and Quantitative Measurements of Fluorescence Intensity, which should help implement standardization not only in cytometry, but in other fields in which fluorescence quantitation is becoming of interest, e.g., microarray analysis. A brief prospectus was provided in 2000 by three key players in the NIST and NCCLS projects<sup>2581</sup>.

## 7.8 NUCLEIC ACID SEQUENCE DETECTION

Figure 7-20 provides a relatively dramatic illustration of the combination of molecular biologic techniques with flow cytometry for detection of specific nucleic acid sequences. The figure shows a small population of CD4-positive lymphocytes containing HIV-1 viral nucleic acid, as detected by Patterson et al<sup>1403</sup> using fluorescein-labeled oligonucleotide probes after *in situ* PCR amplification.

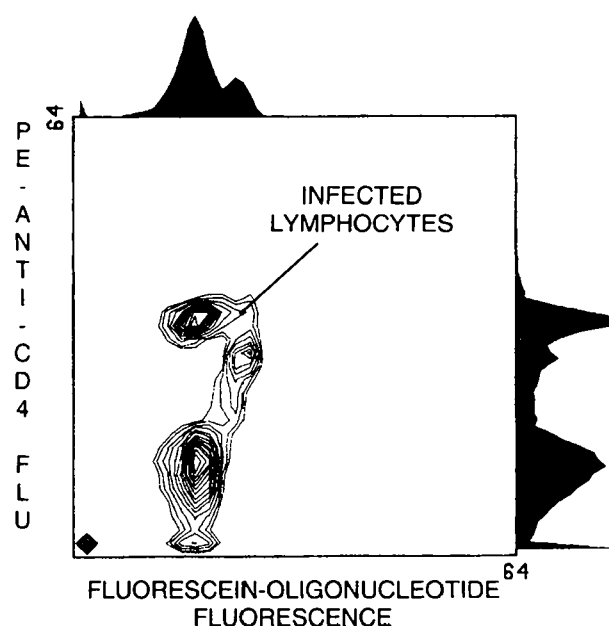

Figure 7-20. Two-dimensional contour plot of log PE-anti-CD4 fluorescence vs. log of fluorescence of fluorescein-labeled oligonucleotide probes specific for HIV-1 nucleic acids, showing oligonucleotide probe fluorescence in some of the CD4-positive lymphocytes after *in situ* PCR of viral sequences<sup>1403</sup>. The figure was provided by Charles Goolsby of Northwestern University.

Detection of sequences by flow cytometry after **Fluorescent *In Situ* Hybridization (FISH)** was described by Trask et al<sup>902</sup> in 1985. Between then and the time the previous edition of this book appeared, a variety of methods to attach fluorescent labels to probes were tried and described. Bauman, Bayer, and van Dekken<sup>1404-5</sup> detected poly-(A)+ RNA using a poly-biotin-d(U)-tailed oligo-d(T) probe and streptavidin-fluorescein; nuclei were stained with DAPI to provide a trigger signal. Amann et al<sup>1406</sup> used detection of

specific ribosomal RNA sequences, present at the level of several thousand copies per cell, for bacterial identification, initially employing probes end-labeled with a single molecule of tetramethylrhodamine. Some signal amplification was obtained by substituting digoxigenin-labeled probes, which were rendered fluorescent by attaching fluoresceinated anti-digoxigenin antibodies<sup>1407</sup>. However, this made it somewhat more difficult to get probe and label through bacterial cell walls. Oligonucleotide probes end-labeled with single molecules of fluorescein and tetramethylrhodamine could be used for two-color analysis; the addition of more molecules of label per probe molecule increased signal, but decreased signal-to-noise due to increased nonspecific binding<sup>1408</sup>.

Timm and Stewart<sup>1409</sup> discussed procedural aspects of "Fluorescent *In Situ* Hybridization En Suspension" (FISHES), including preparation of digoxigenin-labeled probes and staining and washing steps; they found that washing with a solution containing formamide and bovine serum albumin reduced cell loss. Lalli et al<sup>410</sup> also discussed optimization of the preparative procedures. Bardin et al<sup>1411</sup> noted that biotin could be attached to the 5' as well as to the 3' end of oligonucleotide probes, offering some potential for increasing signal when fluorescent streptavidin is attached.

Bains et al<sup>1412</sup> described PRINS (Primed *In Situ* labeling) to quantify poly-A and histone messenger RNA in cells. Poly(A) mRNA was labeled by incorporation of fluoresceinated nucleotides into cDNA chains generated by reverse transcription from the site of oligo(dT) primer-specific annealing on the poly(A) template.

While the sea of literature threatened to become filled with TOADFISH (Totally Outlandish Acronyms Describing Fluorescent *In Situ* Hybridization), this didn't stop a lot of people for going after the big game, which certainly includes detection of low copy numbers of viral gene sequences in infected cells. When the previous issue of this book appeared, this required amplification of those sequences by *in situ* PCR<sup>2708,9</sup>, as was done in the cells used to generate Figure 7-20. Surpassing even this feat of genetic engineering, Embleton et al<sup>1413</sup> reported that it was possible to separately produce and assemble amplified heavy and light chain DNA by PCR and subsequent primer additions in cells in suspension. Long et al<sup>1414</sup> examined *in situ* PCR on slides and in cell suspensions and found that results were comparable; nonspecific results were less frequent with cell suspensions.

Mirsky et al<sup>1415</sup>, using conventional methods of detecting DNA after sorting single cells into microtiter plates, reported that the operational sensitivity of *in situ* PCR for detection of bovine leukemia virus was 90% when testing single infected cells. In addition, they were able to reliably amplify DNA from a single infected cell among as many as 10<sup>5</sup> uninfected cells and established that the sensitivity for detecting a single infected cell among 20, 100, or 1000 uninfected cells was at least 90%. This work put the concept of detecting small numbers of virus-infected cells directly by fluorescence flow cytometry following *in situ* PCR on a firm footing.

In a more mundane but possibly more practical application of genetic sequence detection by flow cytometry, van Dekken et al<sup>1416</sup> used labeled chromosomal probes to discriminate bladder cancer cells with monosomy-9 from stromal cells, enabling determination of the tumor cell kinetics by gated analysis of BrUdR incorporation.

If immunofluorescent staining has pretty much been reduced to cookbook procedures, nucleic acid probe staining may be said to still require both technical skill and FISHer's luck (FISHerperson's luck, if you insist). Andreeff and Pinkel have edited a big book on basic principles and clinical applications of FISH<sup>2710</sup>.

In recent years, it has become possible to use tyramide signal amplification (p. 344) in FISH; new probe labeling techniques<sup>2671,2711-2</sup> can reduce or eliminate nonspecific background fluorescence, making it possible to detect a few dozen copies of a sequence in cells.

### Peptide Nucleic Acid (PNA) Probes

A new class of probes, **peptide nucleic acid (PNA)** probes<sup>2713,4</sup>, appear to offer some significant advantages for cytometry, but clearly have a potential range of applications that extends far beyond this field.

A PNA molecule is comprised of the same purine and pyrimidine bases as are found in nucleic acids, attached to a pseudopeptide with amide or peptide bonds forming the backbone of the polymer, rather than sugars linked by phosphates. PNA molecules are insensitive to digestion by proteases and nucleases, and bind to DNA and RNA; a strand of PNA complementary to a region of double helical DNA will disrupt the double helix and bind to it, displacing its complementary strand. PNAs have been used in experiments on antisense therapy; some short sequences can enter intact cells, while others can be transported inside cells by carrier peptides. PNA probes tagged with thiazole orange or a homologue are nonfluorescent, but become fluorescent on hybridization with nucleic acid; PNA probes incorporating a fluorescent label and a quencher also become fluorescent on hybridization. Less stringent conditions are required for PNA probe hybridization than for hybridization with oligonucleotide probes.

I can leap into fantasy and envision using PNA probes to do FISH on living cells, which can subsequently be sorted. In the real world, PNA probes have been applied to identification of microorganisms based on rRNA sequences<sup>2714</sup> and to determination of telomere length<sup>2715,6</sup>, both of which will be discussed in Chapter 10.

## 7.9 PROBES FOR VARIOUS CELL CONSTITUENTS

### Surface Sugars (Lectin Binding Sites)

The specificity of binding of various **lectins** to different carbohydrate moieties of cell surface and other glycoproteins was appreciated well before the first fluorescence measurements were made in a flow cytometer. In the early 1970's, as flow cytometry began to become popular, the use of lectins

as reagents for characterization of cell surfaces was logical and attractive; before the advent of monoclonal antibodies, no immune reagents were nearly as well defined, chemically or functionally, as were lectins. In addition, the mitogenic activity of lectins such as **concanavalin A (con A)**, **phytohemagglutinin (PHA)**, and **pokeweed mitogen (PWM)**, and reports of different patterns of lectin binding in normal and transformed cells, suggested that quantitative analysis of lectin binding to cells might provide valuable information in research and clinical laboratories.

The first reported flow cytometric analyses of lectin binding to cells were done by Kraemer et al<sup>1310-2</sup> at Los Alamos, who examined binding of fluorescein-con A conjugates. In the initial study, fluorescence was the only cellular parameter measured, and it was difficult to resolve the weak fluorescence of fluorescein-con A above background noise. Later work was done with a multiparameter instrument, in which cell volume measurements were used to gate fluorescence measurements, improving discrimination of cell-associated fluorescence from noise. Analog electronics were used to compute the 2/3 power of cell volume, a quantity proportional to cell surface area, and to derive a measure of the cell surface density of lectin binding sites from the ratio of the fluorescence signal to the derived surface area.

Another relatively early paper<sup>313</sup>, published by Bohn in 1976, described the use of a dye exclusion technique with two-color fluorescence measurement to discriminate between intact cells, to the surfaces of which lectin binding was measured, and cells with damaged membranes. In this paper, Bohn also pointed out that the capability of flow cytometry to precisely measure cell-associated ligand in cell suspensions from which unbound ligand had not been removed by washing could be useful in the analysis of many types of **ligand-receptor interactions**. Both Bohn's work and that of Kraemer et al were considerably more sophisticated than most of what was in print when they were published, and were probably not widely appreciated on that account.

While the present emphasis on analysis of cell surface structures with antibodies has decreased interest in the use of labeled lectins, the latter can still be used effectively as aids in enumeration and separation of cell subpopulations. Measurements of lectin binding have typically been used with measurements of other parameters for this purpose. For example, Nicola et al<sup>179</sup> used measurements of forward light scattering and of the fluorescence of fluorescein-PWM and rhodamine-labeled antineutrophil serum to separate hematopoietic progenitor cells from murine fetal liver, while Bauman et al<sup>1417</sup> purified murine stem cells and committed progenitors using a combination of wheat germ agglutinin and monoclonal antibodies. The anti-H lectin identifies nucleated and non-nucleated erythrocytes<sup>1418</sup>; other lectins have been described as markers for eosinophils<sup>1419</sup>, and so on.

Lectin binding has also been applied to flow cytometric analysis of parasites<sup>1420-1</sup> and to subcellular organelles; Guasch, Guerri, and O'Connor<sup>1422,2717</sup> have examined lectin binding to Golgi fractions from rat liver. Others have exam-

ined changes in lectin binding before and after physiologic changes induced in cells, e.g., by cell-cell and cell-cytokine interactions<sup>1423-6</sup>.

Lectin binding patterns change during immortalization and neoplastic transformation of cell lines<sup>1427</sup> and, conversely, during induced differentiation of tumor cells<sup>1428</sup>; heterogeneity of tumor cells<sup>1429</sup> may reflect different propensities of different cells for metastasis, which has been shown to be related to expression of cell surface glycoproteins that are themselves lectins<sup>1430-2</sup>.

Because lectins are polyvalent, they have a somewhat greater tendency to agglutinate cells than do antibodies. McCoy et al<sup>784</sup> describe a method for blocking all but one active site of a fluoresceinated lectin to produce a monovalent label. The extent to which this technique may be generalized is not completely clear; however, monovalent, monomeric derivatives of lectins may be produced by other chemical means<sup>1433</sup>. Some formal chemistry can be done with lectins on cell surfaces; sugar competition assays can be used to define binding affinities<sup>1434</sup> and sites<sup>1435</sup>.

Reagents for anyone interested in future work along these lines, in the form of fluorescent conjugates of a good selection of lectins, are available from a number of sources (e.g., Molecular Probes and Polysciences). I haven't found recent general review on the use of lectins in flow cytometry; there is a 1987 paper by McCoy<sup>1436</sup>.

### Analysis of Total Cellular Carbohydrate Content

While lectins bind specifically to particular carbohydrates, they cannot effectively be used as reagents for determination of total cellular carbohydrate content. Instead, Duijndam and van Duijn<sup>1437</sup> employed a technique well known in classical histochemistry, the **periodic acid-Schiff reaction**, to determine the carbohydrate content of erythrocytes. Periodic acid oxidation was followed by pararosaniline staining, providing a strong enough fluorescence signal to allow measurement by flow cytometry. Dimethylsuberimide fixation was used and yielded low autofluorescence and only faint staining of unoxidized cells. This methodology should be generally applicable.

### Specific Detection of Cellulose

Taylor et al<sup>2718</sup> have shown that a cellulase and an isolated bacterial cellulose binding domain (CBD) conjugated to fluorescent dyes can be used for specific detection of cellulose by flow cytometry or laser scanning cytometry.

### A Probe for Cell Surface Aldehydes

In conjunction with studies on the mechanism of lymphocyte mitogenesis by compounds that produce oxidation at sites in the cell membrane, Roffman and Wilchek<sup>390</sup> synthesized a **fluorescein diaminobutyryl hydrazide** that could be used for quantitative determination of **aldehydes** in the membrane. They found, incidentally, that the mitogenic activity of different oxidizing agents was not correlated with the degree of aldehyde formation.

## Probes for Lipids and Cholesterol

### Nile Red

Greenspan et al<sup>1402,3</sup> described Nile red, an oxazone prepared from the oxazine dye Nile blue, as a fluorescent stain for **neutral lipids** in cells and tissues. The dye fluoresces yellow when dissolved in neutral lipids, and red when in more polar lipids, e.g., phospholipids; its fluorescence is quenched in aqueous solution. Nile red can be excited at 488 nm; fluorescence of the lipid-bound dye is typically measured at about 550 nm. Dive et al<sup>1438</sup> used Fourier transform flow cytometry<sup>1140</sup> to detect emission spectral changes in Nile red in differentiating ovarian granulosa cells; the fluorescence component related to lipid droplets increased with maturation. While the Fourier transform technique is not accessible to most investigators, Smyth and Wharton<sup>1439</sup>, examining differentiating adipocytes, found that the ratio of gold to red fluorescence from Nile red also reflects the accumulation of cytoplasmic lipid droplets, and can be used to define cells as being differentiated or undifferentiated. Brown, Sullivan, and Greenspan<sup>1440</sup> reported that flow cytometry of Nile red fluorescence could distinguish macrophages bearing orange-colored phospholipid inclusions from control alveolar macrophages, in which yellow-gold fluorescence from the neutral lipid droplets predominates. Nile red has lately been used to quantitate polyhydroxyalkanoic acids in bacteria<sup>2719,20</sup>.

### Filipin

Muller et al<sup>804</sup> reported in 1984 that the polyene antibiotic **filipin**, which was known to form fluorescent complexes with **membrane-associated cholesterol**, could be used for quantitative flow cytometric analysis of unesterified cholesterol in formaldehyde-fixed cells. Kruth et al<sup>805</sup> used filipin staining to detect and isolate cholesteryl ester-containing "foam" cells from atherosclerotic aortas by flow cytometry. Filipin is excited in the UV; fluorescence is measured between 510 and 540 nm. Hassall<sup>1441</sup> used a combination of cyanine dye-labeled low-density lipoprotein (LDL) to measure lipoprotein uptake, Nile Red to measure cholesteryl ester accumulation, and filipin to study free cholesterol homeostasis in a multiparameter analysis of human foam cell-forming macrophages. Hassall and Graham<sup>3721</sup> found that changes in filipin fluorescence correlated with changes in cholesterol biosynthesis in these cells.

### Lipid Droplet Detection Using Scatter Signals

Suzuki et al<sup>1442</sup>, studying triacylglycerol accumulation in cytoplasmic lipid droplets in the U937 macrophage-derived cell line, found that the extent of lipid droplet formation in each cell could be assessed in the absence of any staining by changes in the intensity of 90° light scatter; using the scatter measurement might save you a fluorescence channel if you're running short.

## Probes for Cytoskeletal Organization/Actins

Wallace et al<sup>622</sup> used the fluorescent probe **NBD-phalloidin** for flow cytometric analysis of changes in **cytoskeletal organization** (in particular, changes in actin conformation) in blood neutrophil granulocytes following exposure to chemotactic peptides. This material is available from Molecular Probes. Phalloidin binds to F-actin; deoxyribonuclease I (DNase I) binds to G-actin, and Haugland et al<sup>1133</sup> have shown that the two types of actin can be analyzed simultaneously in cells using **BODIPY-phalloidin** and **fluorescein-DNase I**, both available from Molecular Probes.

### 7.10 TIME AS A PARAMETER: KINETIC MEASUREMENTS

Flow cytometry can be used for quantitative analyses of the degree to which almost any fluorescent substance associates with cells, whether the material is bound to the cell surface or is taken into the cell; it is often useful to examine the processes of binding, uptake, and efflux over time.

When the material is taken up over a period of hours, it is customary and sensible to examine cell samples at intervals. When uptake occurs over a period of seconds to minutes, the speed and throughput of flow cytometry can be utilized to best advantage if a single sample is analyzed continuously, and the time at which each cell arrived at the observation point is recorded with the values of scatter, fluorescence, and other more conventional cytometric parameters. I have alluded to the existence of **kinetic measurements** on p. 2, and, on pp. 177-8, mentioned the fact that the more sophisticated varieties may require nonstandard hardware.

I will stress here, as I did on p. 2, that, while kinetic measurements in flow cytometry are based upon measurements of single cells, the temporal patterns obtained represent data from successive cells in the same sample. We measure cell 1 at time 1, cell 2 at time 2, ... , cell  $n$  at time  $n$ , and make the assumption that cell 1, had we been able to bring it back into the flow cytometer and remeasure it at time  $n$ , would have looked more or less the same as cell  $n$  did. If that assumption holds, we can expect a flow cytometric kinetic measurement to provide more or less the same results as might be obtained from multiple sequential microphotometric measurements of the same cell. If not, we will have to resort to a technique such as scanning laser cytometry, which will allow us to observe the same cell repeatedly over time, to get the kinetic data we need.

Measurements of fluorescence versus time can, as should be obvious, be used to analyze the kinetics of efflux or dissociation of fluorescent material from cells<sup>347</sup>, as well as the kinetics of binding and/or uptake. The time measurement technique is also applicable to studies of enzyme kinetics, in which development of color or fluorescence in cells as a result of enzyme action on chromogenic<sup>348</sup> or fluorogenic substrates is followed over time, and is essential in analyses of other rapidly changing functional parameters such as membrane potential and cytoplasmic calcium ion concentration.

The first publication on time measurement in flow cytometry was by Martin and Swartzendruber; it appeared in 1980<sup>346</sup>.

Figure 7-21 is a typical display of data from a timed measurement; it shows changes in cytoplasmic  $[Ca^{2+}]$  over a period of about 200 seconds following stimulation of T-lymphoblastoid cells with a mitogenic monoclonal antibody.

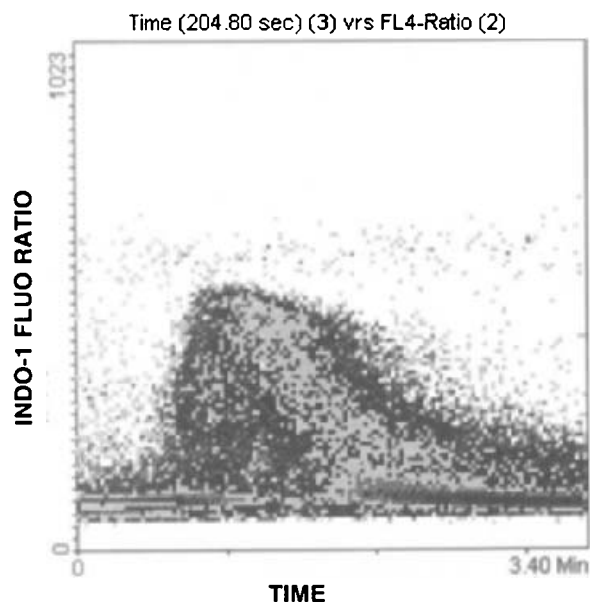

Figure 7-21. Plot of cytoplasmic  $[Ca^{2+}]$ , as indicated by indo-1 fluorescence ratio (pp. 47, 403-4), versus time in T lymphoblastoid cells following stimulation with OKT3 antibody to the T cell receptor. Data were provided by Keith Kelley (Miles Research Center).

Note that while most of the cells represented in Figure 7-21 appear to change their cytoplasmic calcium concentration in response to the applied stimulus, there is considerable heterogeneity in the degree of response. This pattern is not uncommon in kinetic measurements of functional parameters; data from fluorescent ligand binding to ostensibly homogeneous cell populations usually produces nicer looking curves.

The time measurement implemented by Martin and Swartzendruber<sup>346</sup> relied on a linear ramp generator to produce a voltage that increased as a linear function of time; this voltage was used in lieu of a detector signal as an input parameter for the data analysis system. It is now more common to use digital timers, the outputs of which can be read by the data acquisition hardware, for time measurements. Kachel et al<sup>811</sup> and Beumer et al<sup>812</sup> have described digital timing circuitry for collecting kinetic data; such circuits, some of which make use of the real-time clock incorporated in the computer system<sup>813</sup>, are now available in most commercial flow cytometers.

A crude estimate of cells' arrival times in systems that lack a time parameter can be obtained by simply plotting events in the order in which they occurred; this makes the

erroneous assumption that cells arrive at evenly spaced intervals, and Lindmo and Fundingsrud<sup>351</sup> showed that this was very much not the case (see pp. 144-5). Nonetheless, if your instrument hasn't got a time parameter, erroneous assumptions may be better than nothing at all. Some third-party data acquisition systems and add-ons for older instruments add time measurement capability.

### Sample Handling for Kinetic Measurements

When the events being monitored in flow cytometric kinetic studies occur over very short time periods, it is desirable to be able to minimize the delay between the start of sample incubation and the passage of the first cells through the observation point(s) of the flow cytometer. Sample handling systems to permit rapid kinetic analysis by flow cytometry have evolved over the years<sup>349-50,810,1532-4</sup>. A commercial version of Kelley's system<sup>1533</sup>, available from **Cytek Development**, provides mixing and temperature regulation in a unit that mounts close to the nozzle holder for reduced transit times, and allows stimuli to be added to a sample with observation of results within 1 second. An electronic circuit activated at the time of injection generates a data time stamp for direct correlation of injection and cellular response.

Dunne<sup>1534</sup> emphasized the importance of **time window analysis**, also called **fixed-time flow cytometry**, in which each cell reaches the observation point in a controllable, fixed time after a stimulus is added, in studies of rapid cellular responses; this can be achieved by allowing the cell sample and the solution containing the stimulus to mix in a T-junction upstream from the nozzle; the time between stimulation and observation is varied by adjusting the pressure and the length of tubing between the mixing junction and the observation point. Tárnok<sup>2722-3</sup> describes a relatively simple mixing device for time window analysis that he has used to study calcium transients in neuronal cells, and to sort cells with unusual patterns of calcium response. The constant pressure maintained by his mixing arrangement is essential for neuronal cells, because they undergo calcium shifts in response to pressure changes that may occur in syringe pump-driven mixing apparatus.

John Nolan, Larry Sklar, and their collaborators at Los Alamos and the University of New Mexico have been involved for some years in efforts to increase both the time resolution of kinetic measurements and the sample throughput of flow cytometers. They have optimized nozzle design parameters for stream-in-air instruments to stabilize flow in the shortest possible time (Graves et al<sup>2454</sup>, p. 170), and refined mixing apparatus hardware and control software to reduce the interval between mixing and analysis from 300 ms to 55 ms<sup>2460-1</sup>. They have also developed a dynamic temperature regulation unit that provides more accurate maintenance of sample temperature than was previously possible, and also permits analysis of cellular and chemical responses to rapid temperature changes<sup>2427</sup>.

With a view toward improving sample throughput as well as refining kinetic measurements, Durack et al<sup>1535</sup> devel-

oped the technique of **time interval gating** to allow data from kinetic experiments involving multiple samples, each of which is measured briefly (i.e., for a few seconds) at intervals of several minutes, to be collected in a single large list mode data file, facilitating subsequent analysis of the data.

The technology of **flow injection analysis**, a rapid analytical chemical method pioneered by Ruzicka<sup>147</sup>, has been applied by him and his colleagues to cytometry<sup>1148-9,1536</sup>. Their methodology uses computer-controlled systems of pumps and valves to handle samples, and software to facilitate non-equilibrium analysis.

Sklar et al<sup>12452,3</sup> have also developed systems for **high throughput flow cytometry**; the most advanced<sup>12463</sup> introduces 1-3  $\mu\text{L}$  "slugs" of sample, interspersed with air bubbles to reduce sample carryover, into the cytometer at a rate of one sample every 1.3 seconds. The MoSkeeto<sup>TM</sup> sampler now offered by **DakoCytomation** appears to be a commercial version.

### Time as a Quality Control Parameter

Watson<sup>8,9</sup> cleverly extended the earlier observations of cell arrival times<sup>351</sup> to permit the use of **time measurements for quality control** within individual sample runs. The interval between cell arrival or acquisition times is used to derive a real-time measurement of **sample flow rate**, which is displayed against time; in addition, a measured parameter of interest (DNA content, in the case illustrated in Figure 7-22) is shown (schematically) vs. time in a two-dimensional display.

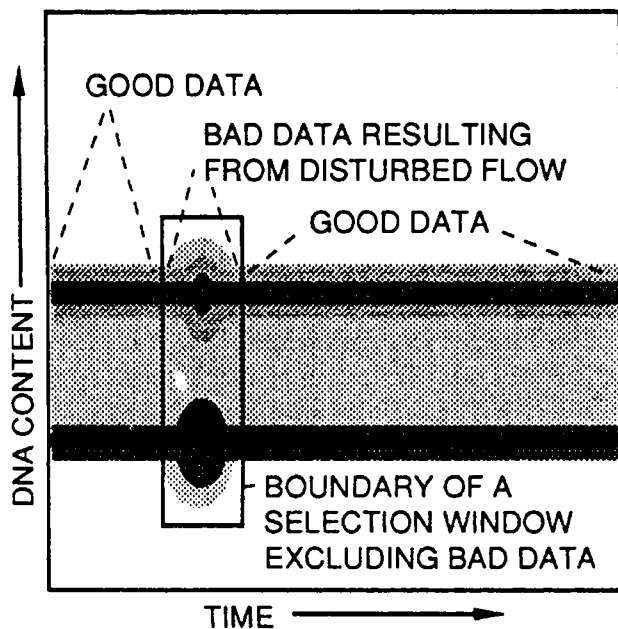

Figure 7-22. Time used as a quality control parameter in DNA content analysis (after Watson<sup>89</sup>).

The "lumps" in the middle of the display result from a temporary degradation in measurement precision caused by a

transient disturbance of the flow pattern. Before and after the transient, the measurement precision is considerably better. However, if the DNA content distribution were calculated for the entire sample, the coefficient of variation would be increased by inclusion of the relatively small number of cells from which data were acquired during the flow disturbance. By defining a selection window as shown in the figure, it is possible to exclude the bad data points from the DNA content distribution. In many cases, e.g., when one analyzes cells from a very small sample of tumor tissue, being able to "rescue" data in this fashion may make the difference between getting and not getting enough information to characterize a specimen. Even when there is plenty of sample available, however, Watson's technique provides a convenient means of assessing the quality of measurements. Kusuda and Melamed<sup>2725</sup> used the chronological order of events in a list mode file as a time parameter and were able, in some cases, to correct for drift in data values.

### Sloowwww Floowwww

Conventional flow cytometers use flow velocities of 1-10 m/sec, making it almost impossible to examine the same cell twice at time intervals separated by more than a few hundred  $\mu\text{sec}$ . The relatively high flow velocities also result in shear stress on cells in the sample, making the use of flow cytometry for studies of cell adhesion suspect.

Amblard et al<sup>1557</sup> developed a chamber for flow cytometric analysis over an extended range of stream velocity which, with adaptations to the electronics, permitted standard analysis at velocities as low as 0.01 m/sec in a B-D FACS instrument. Conjugates formed by the adhesion between human B and resting T lymphocytes, disrupted in conventional flow cytometers, could be detected and precisely quantified provided analysis velocity was kept below 0.1 m/sec. A much longer chamber, operating at this velocity, with widely separated measurement stations, could allow multiple observations of an individual cell to be made over periods of tens to hundreds of seconds; nobody seems to have built one yet. However, slow flow systems are in use for such applications as DNA fragment sizing, which will be discussed in Chapter 10.

### 7.II LABELED LIGAND BINDING

The flow cytometric analysis of ligand binding to cell surface and intracellular receptors, or to receptors on beads or other particles, can be approached in several ways, the most obvious of which is probably the use of labeled ligands. To produce labeled ligands, you need to have enough relatively pure unlabeled ligand on hand to yield an adequate supply of labeled material for your experiments. Acquiring the starting material used to be the first hard part of the project; the second part was verifying that labeling the ligand didn't drastically alter its binding characteristics. In this age of cloning, a respectable variety of labeled ligands such as cytokines and hormones are available off-the-shelf, and you probably won't have to worry about getting and labeling

your ligand; if not, this isn't the place to look for help. This is a good place to mention that antibodies also count as ligands; their binding to cells can be analyzed using exactly the same techniques.

The production of labeled ligands, and the flow cytometric analysis of ligand binding, have become so common that I have given up trying to keep track of every ligand. Any listing or tabulation you see will be incomplete by the time it appears; I've run across several papers on flow cytometry of ligand binding that didn't turn up in my literature search on flow cytometry. As was the case with immunofluorescence, I'll have to stick to the basics with selective excursions into specifics.

Just as **cell surface receptors** for ligands ranging from small peptide hormones to viruses and bacteria can be demonstrated by flow cytometry using fluorescently labeled analogues, **cytosolic** and **nuclear receptors** for ligands such as steroid and thyroid hormones may also be demonstrable. However, since the ligands themselves are relatively small molecules, it is, in general, more difficult to find or synthesize analogues with binding characteristics similar to those of the natural ligands than to prepare usable fluorescent derivatives of larger molecules. In order to demonstrate receptors within intact cells, the fluorescent ligand used must obviously have the capability of crossing or being carried across the cell membrane, as well as the binding characteristics previously mentioned. The size and specificity constraints on analogues make it infeasible to attach more than one fluorochrome moiety to each molecule of ligand; since the number of intracellular receptor sites is generally small, one can therefore expect only weak fluorescence signals at best from cells stained with the labeled ligand analogue.

The flow cytometric literature in this area recounts numerous attempts at demonstration and quantitation of **estrogen receptors** in cells. The presence or absence of estrogen receptors, as determined by radioligand binding analysis of biopsy specimens, is of significance in assessing prognosis and planning therapy of breast cancer. Fisher et al<sup>378</sup>, using fluoresceinated estrone (17-FE) and fluorescence microscopy, demonstrated heterogeneous binding patterns of the material in tissue samples; Tyrer et al<sup>379</sup>, Kute et al<sup>380</sup>, and Van et al<sup>381</sup> made flow cytometric measurements using 17-FE and other fluorescent analogues.

A study by Benz, Wiznitzer, and Lee<sup>828</sup>, who utilized bovine serum albumin (BSA) as a carrier molecule to which an average of 25 estradiol and 4 fluorescein molecules were bound, generated a heated exchange of correspondence between Ashcroft<sup>829</sup> and Benz<sup>830</sup>, which did not resolve the issue of how accurately one can study binding sites for small molecules using much larger ones. If you simply want to determine the number of binding sites, **anti-receptor antibodies** may be preferable to labeled ligand analogues as reagents, but, if the objective is to measure binding affinities, you may be literally and figuratively stuck with labeled ligands. On the bright side, Marchetti et al<sup>1443</sup> found comparable results in analyses of **glucocorticoid receptors** using

flow cytometry with antireceptor antibodies and fluorescein-labeled steroid analogues and classical radioligand binding methods.

### Labeling Strategies

The procedure described by Shechter et al<sup>302</sup>, in which small peptide hormones such as insulin are fluorescently labeled by reaction with fluorescein- or tetramethylrhodamine-labeled **lactalbumin**, provides a way of getting a few more fluorescent molecules onto a ligand than can be done by direct labeling. This becomes important when the number of binding sites per cell is small; under these circumstances, flow cytometry may allow detection and quantitation of amounts of bound ligand too small to be seen under the fluorescence microscope. This degree of sensitivity is also associated with the technique of **video intensification microscopy (VIM)**<sup>445-6</sup>, which offers the advantage of allowing the same cell to be observed over a period of time. A paper by MacInnes et al<sup>447</sup> illustrates the use of VIM and cell sorting in a complementary fashion to study luteinizing hormone releasing hormone binding sites on rat pituitary cells.

When the ligand for which receptors are to be demonstrated is a small molecule, covalent attachment of ligand molecules to a fluorescently tagged protein, or, alternatively, a phycobiliprotein, may yield a material that will still bind specifically to receptors, thereby enabling attachment of more than a single fluorochrome moiety to each receptor site. This technique was used by Osband et al<sup>448</sup> to show that a subpopulation of T cells bore H<sub>2</sub> (cimetidine-reactive) histamine receptors; the reagent employed was a conjugate of histamine with fluoresceinated albumin. Hallberg et al<sup>449</sup> used the same material to demonstrate H<sub>1</sub> and H<sub>2</sub> receptors on platelets; Muirhead et al<sup>849</sup>, however, found only nonspecific binding of similar conjugates to lymphocytes.

### Formal Analysis of Ligand Binding

Bohn<sup>313,326-7</sup> was probably the first to appreciate that flow cytometry could be used for **quantitative analyses of fluorescent ligand binding** to cells that yielded essentially the same data as were obtained from conventional radioligand binding assays; in some circumstances, bulk fluorimetry must be used in addition to flow cytometry for precise determination of the ratio of bound to unbound ligand, but, in other cases, information can be derived solely from flow cytometric data.

The flow cytometric method offers a particular advantage over radioisotope techniques in that the binding equilibrium is not disturbed because there is no need to wash away unbound ligand; the speed of the flow cytometric analysis and the elimination of the necessity to deal with and dispose of radioactive materials also weigh in its favor. Sklar and Finney<sup>450</sup> demonstrated the capabilities of flow cytometry in an analysis of steady-state binding of a fluoresceinated chemotactic peptide to neutrophils.

The study of Benz, Wiznitzer, and Lee<sup>828</sup> on estrogen receptors provides good examples of the calculation of binding

affinities and the construction of the **Scatchard** and **Lineweaver-Burk plots** commonly used with radioligand assays. Other older examples of quantitative analysis, dealing with binding of antibodies to cell surface receptors, were published by Uckun et al<sup>1444</sup> and Krause et al<sup>1445</sup>; Ziegler et al studied labeled **insulin**<sup>2313</sup>. In addition, Chatelier and Ashcroft<sup>797</sup> proposed an alternate method, **isoparametric analysis**, for determining ligand-binding characteristics.

More recently, Gordon<sup>2726</sup> described a Scatchard analysis of **concanavalin A** binding to lymphocytes, noting that cytometric plots seemed more precise than those obtained using radiolabeled ligands, particularly at low ligand concentrations. Macho<sup>2727</sup> et al quantified **fatty acid** binding to cells using a BODIPY-labeled dodecanoic acid. Cherukuri et al<sup>2728</sup> used flow cytometry, fluorescence spectroscopy, and two-photon microscopy in an elaborate mechanistic study of binding and internalization of fluoresceinated poly-D-lysine by murine macrophages. Waller et al<sup>2729</sup> established the fluorescence characteristics of six fluorescently labeled **N-formyl peptides**, which bind to neutrophils, and developed and validated competitive binding protocols to determine binding constants of unlabeled ligands. Lauer et al<sup>2730</sup> performed real-time quantitative flow cytometric analysis of the interaction of fluoresceinated cholera toxin subunits with ganglioside receptors inserted into phospholipid membranes supported by glass beads. All of the reports just described may be helpful to anyone interested in doing quantitative work with other ligands.

### Labeled Ligands versus Anti-Receptor Antibodies

In some cases, there is a choice of labeled ligands available that will bind to a particular receptor; for example, transferrin receptors can be demonstrated using either fluoresceinated transferrin<sup>451</sup> or a monoclonal antibody such as Ortho's OKT9, which reacts with the transferrin receptor<sup>452</sup> (CD71). Flow cytometry can, of course, be utilized to establish the fact that two different ligands do react with the same or closely spaced sites on cell surfaces. Fingerroth et al<sup>453</sup> used flow cytometric analysis to study the binding of fluorescently tagged viruses, antibodies, and complement components to human B cells, and showed that the Epstein-Barr virus binds to the type 2 complement receptor.

### Ligand Binding Detected by Functional Changes

When the ligand of interest is not available in sufficient quantity or purity to permit ligand labeling, the only feasible way to identify cells that have bound and responded to ligand is by demonstrating induced changes in functional parameters. This approach was taken by Price et al<sup>417</sup>, who isolated erythroid and myeloid precursor cells from bone marrow based upon SCM responses to impure preparations of growth stimulatory factors, and by Osband et al<sup>454</sup>, who isolated H<sub>2</sub> receptor bearing T cells based on membrane potential responses to a combination of histamine and an H<sub>2</sub> receptor antagonist. For this approach to work, it is necessary to have stable and reproducible flow cytometric meth-

ods for the detection of physiologic changes induced by ligand binding; while such methods have improved over the years, the methods of preparing labeled ligands and the sensitivity of instruments have also improved, making it easier to detect binding *per se*. However, demonstration of functional changes remains useful for distinguishing between cells that merely bind ligand and cells that respond. Tordai et al<sup>1446</sup>, for example, used binding of labeled antireceptor antibodies and induction of calcium fluxes by unlabeled thrombin to identify functional thrombin receptors on T-lymphoblastoid cells.

### Fluorescent Ligand Binding: Some Examples

**High-density lipoprotein (HDL)** binding was studied by Schmitz et al<sup>1447</sup>, using a rhodamine label; they compared fluorescent and radiolabeled ligand binding and estimated the number of binding sites on human lymphocytes, monocytes, and granulocytes. Traill et al<sup>1448</sup> used "**DiI**" (**diioctadecyl-indocarbocyanine**) to label HDL and quantified its binding to lymphocytes; they also<sup>1449,50</sup> studied binding of DiI-labeled **low-density lipoprotein (LDL)**. Corsetti et al<sup>1451,2</sup> labeled LDL with *N,N*-dipentadecylaminostyrylpyridinium iodide, which has very low fluorescence in aqueous solution and which therefore should yield lower fluorescence background in HDL-binding measurements.

Laborda et al<sup>1453</sup> and Torres et al<sup>1454</sup> examined the binding and endocytosis of fluorescently labeled **α-fetoprotein** and **transferrin** by lymphoid cells. Midoux, Roche, and MonSIGNY<sup>1455</sup> studied binding, uptake, and degradation of fluoresceinated **neoglycoproteins**. Others have used fluorescein as a label for the clotting factor **VIII**<sup>1460</sup>, for **anaphylotoxin C5a**<sup>1461</sup>, and for **low molecular weight heparin**<sup>2731</sup>. Richerson et al<sup>1462</sup> and Sumaroka et al<sup>1463</sup> examined binding of mycobacterial **muramyl dipeptides** to macrophages, while other groups studied binding of bacteria to platelets<sup>1464,5</sup> and gastrointestinal cells<sup>1466</sup>. Szabo and Damjanovich<sup>1467</sup> reported the use of a fluorescein-labeled, protein A-rich strain of *Staphylococcus* as a second-step reagent for immunofluorescence.

While some work has been done with fluoresceinated preparations of the **lipopolysaccharide (LPS)**<sup>1456-9</sup> derived from various species of Gram-negative bacteria, Triantafilou et al<sup>2732</sup> used Alexa 488 hydrazide to label the oligosaccharide core of the material, avoiding interaction of the label with lipid A, which is the portion of the molecule involved in binding. Their labeled preparation can be used at concentrations in the range of those reported to be present in the blood of patients with Gram-negative sepsis.

Indirect staining was used by Gabilovich et al<sup>1468</sup> to quantify binding of the **HIV gp120 protein** to cells; the protein was labeled with biotin and subsequently reacted with Texas Red-streptavidin. Indirect staining also provides amplification to facilitate detection of small numbers of binding sites for **growth factors** and **cytokines**. Wognum et al used biotinylated ligands followed by phycoerythrin-streptavidin to detect receptors for **erythropoietin**<sup>1469</sup> and for

**interleukin-6 (IL-6)**<sup>1470</sup>; further amplification with biotin-anti-phycoerythrin antibody increases the signal for erythropoietin receptor detection<sup>1471</sup>. Biotinylated ligands have also been used to quantify receptors for **IL-2**<sup>1472,3</sup> and **IL-4**<sup>1474,5</sup>, enabling demonstration of fewer than 100 receptor sites/cell in some cases. Lawrence et al<sup>2733</sup> used a fluorescein-labeled high-affinity opioid in studies of the kappa opioid receptor, amplifying signals by staining the bound ligand with a phycoerythrin-labeled anti-fluorescein antibody.

Both direct fluorescent labeling and biotinylation of small molecules may, as mentioned before, result in loss of activity and even in the labeled ligand acquiring the characteristics of an antagonist, as was shown by Helmreich et al<sup>1476</sup>, who fluoresceinated **glucagon** at different sites, and by Newman et al<sup>1477,8</sup>, who made biotinylated derivatives of **parathyroid hormone**. Jans et al<sup>1479</sup> used spacers to preserve biological activity when preparing biotinylated **vasopressin**. In other cases, even small molecules may be labeled without apparent loss of activity and binding specificity; active fluorescein derivatives of **transforming growth factor beta**<sup>1480</sup>, of **chemotactic peptides**<sup>701</sup>, and of the fibronectin peptide **arg-gly-asp-ser**<sup>1481</sup> have been prepared, as has an active fluorescent **NBD-phorbol ester**<sup>1482</sup>. Chianelli et al<sup>1483</sup> have used fluorescence flow cytometry with a labeled antireceptor antibody in competitive assays to determine whether derivatization of IL-2 to various nonfluorescent products affects binding.

Moving from very small ligands to very large ones, I should mention the use of labeled **aggregated human immunoglobulin** in a flow cytometric assay for **circulating immune complexes** based on competitive binding to surface receptors on Raji cells<sup>1484</sup>, and a couple of papers on binding of fluorescein-labeled viruses to cells<sup>1485,6</sup>.

Since ligand binding is one of the phenomena investigated in the context of **high throughput screening** of lead (I don't mean Pb!) compounds in drug development, I should point out that a high throughput flow cytometer could be gainfully employed in this area.

## 7.12 FUNCTIONAL PARAMETERS I

The distinction I have made between structural and functional parameters is, to some extent, arbitrary; it is, after all, the function of cells that determines, maintains, and/or changes their structure. In general, what I have called **structural parameters** describe cells' stable morphologic characteristics and their content of specific chemical constituents, while the classification of **functional parameters** has been reserved for physical and chemical properties of cells which are defined operationally and/or which change rapidly. Both of these characteristics of functional parameters tend to make them more difficult to measure, by flow cytometry or otherwise, than are structural parameters. The motivation to make such measurements is provided by the perceptions that **functional heterogeneity** within cell populations is of biological significance and that observations of their functional characteristics can aid in understanding and predicting cells'

behavior. I'll start with the outside of the cell here and work my way in.

### Cell Surface Charge

Valet et al<sup>322,377</sup> have estimated **cell surface charge** from the binding of **fluoresceinated polycations** to the cell surface. They believe their flow cytometric method can be somewhat more informative than can the conventional measurement of surface charge based upon cells' electrophoretic mobilities, since flow cytometric analysis can be done using labeled polycations of different molecular weights and structures to define the accessibility, as well as the number, of various charged sites on cell surfaces.

### Cell Membrane Characteristics

#### Membrane Integrity versus "Viability": Dye Exclusion Tests

I have discussed **membrane integrity** in connection with vital staining on pp. 299-301. Most people who work with cells are familiar with tests of "viability" based on cells' capacity to exclude acid dyes such as **trypan blue**, **eosin**, **erythrosin**, **nigrosin**, and **primulin** and some basic dyes such as **propidium**. The basis of all of these **dye exclusion tests** is the same; the dyes used are **impermeant**, and do not normally cross intact cell membranes.

A slight variation on the same theme is provided by using **esters of fluorescein** or related compounds as the reagents; **fluorescein diacetate (FDA)**, introduced on pp. 24-7, is lipophilic, uncharged, and nonfluorescent, and thus readily crosses cell membranes. Once inside cells, FDA is hydrolyzed by nonspecific esterases to produce the fluorescent fluorescein anion, which is retained (for a few minutes, at least) by cells with intact membranes and lost by cells with damaged membranes<sup>335</sup>.

When doing dye exclusion tests, bear in mind that **propidium and ethidium are not interchangeable**. Although the two dyes behave nearly identically as intercalating stains for double-stranded nucleic acid, ethidium will enter intact cells slowly, especially if the pH of the medium is high, but is likely to be pumped out by an efflux pump. Propidium, which has one more positive charge, will not enter normally enter intact cells; you should thus use propidium, not ethidium, to test membrane integrity.

In these days of multicolor immunofluorescence measurements, it is preferable to have a dye exclusion indicator that emits at a longer wavelength than propidium; Schmid et al<sup>1516</sup> have shown that **7-amino-actinomycin D (7-AAD)** is useful for this purpose, and the red-excited **TO-PRO-3**, which, like propidium, is doubly charged and impermeant (pp. 300-1), is also useful. In work with bacteria using a dual-laser instrument and adding both dyes to samples, I have noted that cells that take up propidium take up TO-PRO-3 and *vice versa*; I never observed cells that took up only one of the dyes. I have not had the opportunity to play the same game with either propidium or TO-PRO-3 and

**SYTOX Green**, which is a current favorite for membrane integrity testing, especially in bacteria<sup>2734</sup>, and which I suspect has at least three positive charges.

Bhuyan et al<sup>336</sup> and Roper and Drewinko<sup>337</sup>, in papers published in 1976, showed independently that cells treated with lethal doses of cytotoxic drugs remained “viable” by dye exclusion tests for several days, and that the fraction of viable cells estimated by dye exclusion or <sup>51</sup>Cr release<sup>336</sup> was considerably higher than the fraction of cells that retained clonogenicity in culture. **As a general rule, cells that let in trypan blue or propidium are dead, but cells that don’t are not necessarily viable.**

Despite the limitations of dye exclusion tests, there have been a lot of papers published that describe various flow cytometric adaptations and applications<sup>4, 165, 197, 240, 313, 326-7, 338-45</sup>. As might be expected, dye exclusion provides a somewhat more accurate measure of viability when applied to situations in which cells are killed by punching holes in their membranes, e.g., freezing or immune lysis<sup>4, 344</sup>.

Cells that do have holes in the membrane usually admit molecules considerably bigger than dyes, and thus tend to stain nonspecifically with fluorescent antibodies, lectins, etc. If fluorescein is being used to label such ligands, the addition of erythrosin or ethidium (or, preferably, propidium) to the sample produces strong fluorescence in the dead cells, allowing them to be gated out of analyses<sup>165, 313, 326-7</sup>. Khaw et al<sup>342</sup> worked the other side of this street, detecting loss of membrane integrity in cardiac muscle cells by their binding of fluorescent spheres coated with an antimyosin antibody. Stöhr and Vogt-Schaden<sup>339</sup> used a mixture of Hoechst 33342 and propidium to stain DNA in unfixed cells; this allows discrimination of cells with intact (blue fluorescence) and damaged (red fluorescence) membranes. Wallen et al showed that this test, like other dye exclusion tests, does not give a good indication of reproductive viability<sup>345</sup>, reinforcing the conclusions others reached earlier<sup>336-7</sup>.

If you think about it, you’ll probably guess that it is easier to see a cell lightly stained with eosin or propidium, under a fluorescence microscope, than it is to see a cell lightly stained with trypan blue under a transmitted light microscope. This would suggest that dye exclusion tests done by absorption and fluorescence might give different results. During the development of the Block differential leukocyte counter, some comparative studies of trypan blue and ethidium (we didn’t appreciate the difference between ethidium and propidium at the time) exclusion were done; the proportion of damaged cells estimated by ethidium fluorescence was always higher than that estimated by trypan blue absorption, and the ratio of the two remained nearly constant from sample to sample (K. F. Mead, unpublished). Others<sup>807</sup> have made similar observations.

Berglund et al<sup>808</sup> examined the UV-excited, blue fluorescent sulfonated dye **Calcofluor White M2R (CFW)**, an optical brightener closely related to the “LN” used in the Block differential staining system, as a dye for assessing membrane integrity; it works well with animal cells but may

stain the walls of plant cells even when the membranes are intact. There may be some advantage to using CFW or dyes with similar spectral characteristics when one is trying to measure other parameters by green and orange or red fluorescence using 488 nm excitation. However, as a general rule, one can use propidium as a membrane integrity indicator even when utilizing orange fluorescence measurements for other purposes, by adjusting the propidium concentration; if not, 7-AAD (or TO-PRO-3 if you have a red laser and a 488 nm laser) will almost certainly work.

If, for example, you are trying to measure pyronin Y fluorescence in intact cells, adding propidium at a concentration of 1-2 µg/ml to the sample (this is less than 1/20 the concentration at which the dye is commonly used for stoichiometric DNA staining) will produce strong red fluorescence in cells with damaged membranes. If the detector used for the pyronin measurement has a response extending to at least 600 nm, the cells with damaged membranes will show up off-scale in this channel; alternatively, a separate red (600-640 nm) detector could be used. When using cells stained with Hoechst 33342, bear in mind that, if it gets in, propidium will strongly quench the Hoechst dye fluorescence; if you are triggering on the Hoechst dye fluorescence signal, you may have to adjust the threshold accordingly. 7-AAD, in my experience, does not quench Hoechst dye fluorescence to the same extent.

Even if a cell does let propidium or the other “excluded” dyes in, you can’t be absolutely sure it’s nonviable. Cell membranes can be transiently **permeabilized**, not only to dyes, but to macromolecules, by physical or chemical means, as discussed on pp. 300-301, and then resealed with retention of viability - even reproductive viability. If you permeabilize cells in a solution of propidium, reseal them, and add FDA (to a final concentration between 500 ng and 1 µg/ml, from a 0.5-1 mg/ml working solution in DMSO), any cells that weren’t permeabilized will show only green cytoplasmic fluorescence, any cells that didn’t reseal or had damaged membranes to start with will show only red nuclear fluorescence, and cells that were permeabilized and resealed will show green cytoplasm and red nuclei (F. Tsang & H. Shapiro, unpublished). Jones and Senft<sup>809</sup> noted that air-dried smears could be made from cell suspensions stained with FDA and propidium, allowing the fraction of cells with intact membranes to be determined as long as a week after slides are made.

Two compounds closely related to FDA and originally developed for intracellular pH estimation also offer advantages for dye exclusion tests because the fluorescent materials formed from them in cells are lost from the cells much more slowly than is fluorescein. The compounds are **carboxyfluorescein (COF)** and **2’,7’-bis’(carboxyethyl)-5-(6’)-carboxyfluorescein (BCECF)**; they will be discussed in more detail in the section on pH measurement. However, when it comes to dye-exclusion tests, the real champion among fluorescein-based dyes is **calcein**, introduced into cells as the **acetoxymethyl (AM)** ester; once the ester is

cleaved, the free dye stays inside cells much longer than the others (but see pp. 376-7). In general, however, people now seem to use nucleic acid dyes in preference to various fluorescein derivatives for dye exclusion testing, because the objective is often to eliminate dead cells from immunofluorescence analysis, and any of the fluorescein derivatives will produce enough of a green fluorescence signal to make it difficult or impossible to measure immunofluorescence using fluorescein, PE, or even PE tandems.

### Detecting "Dead" Cells in Fixed Samples

Many of the samples now run through flow cytometers have been fixed before they are run. Identification of cells that had lost membrane integrity before fixation is useful, because when a sample is stained with fluorescent antibodies to a cell surface antigen or antigens prior to fixation, antibodies will enter cells with damaged membranes, and those cells will therefore exhibit high levels of nonspecific fluorescence. Riedy et al<sup>1516</sup> developed a method for identification of membrane-damaged cells using the irreversible binding of photoactivated **ethidium monoazide (EMA)**. EMA is a positively charged molecule containing the nucleic acid-binding fluorophore ethidium; it is excluded by "viable" cells with intact membranes and enters cells with damaged membranes. When added to a sample prior to fixation, EMA can be covalently bound to nucleic acids by photochemical crosslinking using visible light. When the samples are subsequently washed, stained with antibodies and fixed, ethidium is retained only in those cells that had damaged membranes prior to fixation; at appropriate levels, the ethidium fluorescence is distinguishable from fluorescein and phycoerythrin emission.

These days, there's an easier way to do things. Schmid et al<sup>1575</sup> found that, if cells were exposed to 4 µg/mL **7-AAD** before fixation, the dye could be kept in only those cells that had lost membrane integrity prior to fixation by addition of 4 µg/mL **actinomycin D (AD)** to subsequent fix, stain and wash solutions and buffers. AD is nonfluorescent, but competes with 7-AAD for binding sites on DNA. The 7-AAD/AD combination was used with fluorescein- and PE-labeled antibodies and TO-PRO-3 (with added RNase) to permit two-color immunophenotyping and DNA content determination in cells that were not membrane-damaged prior to fixation.

### Membrane Fusion and Turnover; Cell Tracking

It is often desirable to be able to attach permanent or relatively permanent fluorescent labels to cell membranes, for such purposes as detecting cell aggregation or hybridization, determining the localization and fate of cells isolated from and reinjected into an animal, and establishing the rate of turnover of various components of the membrane itself. A number of fluorescent compounds have been used for such membrane labeling.

Covalent labels such as FITC and XRITC bind to membrane proteins; Abernethy et al<sup>1540</sup> found that lymphocytes

labeled with both dyes and reinjected into sheep could be followed over periods of days, and that FITC-labeled cells isolated from lymph could be double labeled with XRITC and recovered. Capo et al<sup>1541</sup> noted that there was some non-specific transfer of fluorescein molecules (about 10,000 molecules) from FITC-labeled to unlabeled cells *in vitro*, suggesting that FITC is not the stablest of labels. Weston and Parish<sup>1542</sup> reported that Hoechst 33342-, BCECF-, and calcein-labeled cells could be followed for 2-3 days, while cells covalently labeled with **carboxyfluorescein succinimidyl ester (CFSE)** retained label for weeks.

Another class of labels are incorporated into the membrane lipid bilayer itself. Among the most widely studied are derivatives of cyanine dyes, including "**DiI**" (**dioctadecylindocarbocyanine**) and "**DiO**" (**dioctadecyloxycarbocyanine**)<sup>1543</sup>, both of which can be excited at 488 nm, with DiO emitting green fluorescence at about 500 nm and DiI emitting yellow fluorescence at about 565 nm. Fluorescein and phycoerythrin emission filters are, respectively, well suited for measurement of DiO and DiI. The octadecyl (C<sub>18</sub>) side chains of these probes reside in the lipid bilayer; the chromophores remain at the surface.

When used to label neuronal cells, which do not divide, DiI and DiO persist in the membrane for months; they were found to remain detectable for more than a week in cultured endothelial and smooth muscle cells<sup>1544</sup>. St. John<sup>1545</sup> found that DiI was toxic to embryonic rat neurons, and that the C<sub>12</sub> derivative, which was not, could be used effectively for long-term labeling. Ledley et al<sup>1546</sup> used DiI as a marker to determine localization of transplanted hepatocytes and thyroid follicular cells by flow cytometry.

Paul Horan and his colleagues<sup>1547,52</sup> introduced the **PKH** series of tracking dyes, which includes both radioactively and fluorescently labeled compounds incorporating longer aliphatic chains (e.g., C<sub>24</sub>) than are found in DiI and DiO. Presumably, these molecules incorporate into the outer layer of the lipid membrane bilayer and penetrate into the inner layer, providing stronger binding and, as a result, longer persistence. These dyes have been used to study peritoneal macrophages<sup>1548,9</sup>, to discriminate target from effector cells in cytotoxicity assays<sup>1550</sup>, to track lymphocytes used in adoptive immunotherapy<sup>1552</sup>, and to label bacteria for studies of phagocytosis<sup>1553</sup>. I know of no comparative study of PKH dyes vs. DiI and DiO, but the PKH dyes demonstrably work.

### Cell Proliferation Analyzed Using Tracking Dyes

As Horan et al pointed out<sup>1547</sup>, if a cell labeled with a tracking dye subsequently proliferates, each daughter cell will get approximately half the label; in the next generation, each daughter cell will carry one-quarter of the label, and so on. Analysis of the labeling intensities of cells grown *in vivo* or *in vitro* after labeling will, therefore, allow determination of the number of division cycles through which each cell has progressed since the label was applied. While similar information can be obtained from bromodeoxyuridine labeling

studies, it is much simpler to obtain using tracking dyes. Ashley et al<sup>1354</sup> used the yellow-fluorescent dye PKH26 GL to follow leukemic cells through several cell divisions; more recently, Yamamura et al<sup>1555</sup> developed a method for analysis of proliferation of stimulated lymphocytes using the same dye. Results are shown in Figure 7-23.

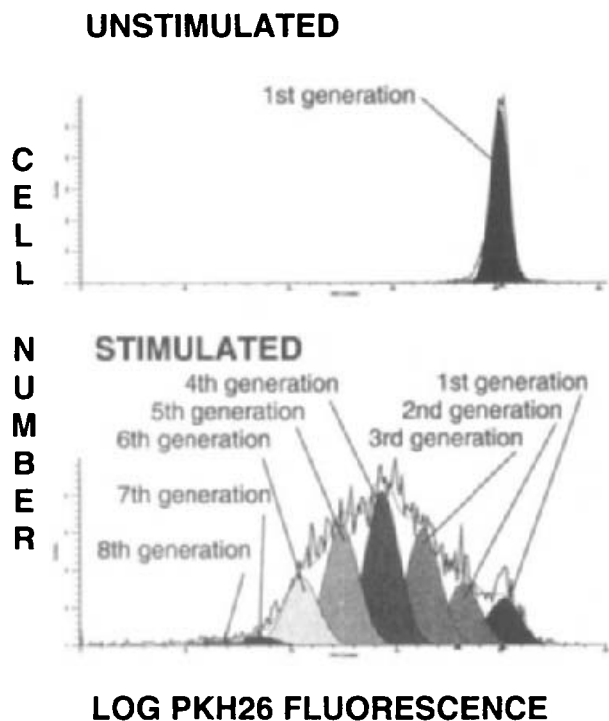

Figure 7-23. Cell proliferation indicated by dilution of fluorescence of the tracking dye PKH26 in mitogen-stimulated and unstimulated peripheral lymphocytes after 5 days in culture<sup>1555</sup>. The data and figures were provided by Yasuhiro Yamamura (Ponce (PR) School of Medicine), Abraham Schwartz (Flow Cytometry Standards Corp.), Bruce Bagwell, and Don Herbert (Verity Software House).

The raw histograms in the figure were analyzed using a variant of the ModFit DNA analysis program from **Verity Software House**, which does nonlinear least squares fits to decompose a histogram into a sum of distributions representing successive generations of daughter cells. The model can identify as many as ten successive generations of cells. This cannot be done using BrUdR or tritiated thymidine; the tracking dye technique also has the advantage of being usable with live cells, permitting sorting of cells in different generations. The PKH dyes and analysis software are available from **Sigma**.

Tracking dyes are particularly useful for analysis of responses of lymphocytes to antigens. When mitogens are used for lymphocyte stimulation, a majority of cells respond. In antigen stimulation, the fraction of responsive cells ranges from 1 or 2 percent, in mixed lymphocyte reactions, to one cell in several hundred thousand, which is typical when cells

are exposed to viral antigens. In a lymphocyte population, there should be a spectrum of affinities for a particular antigen; cells that begin proliferating earlier may have different characteristics from those that begin proliferating later. This could be established by sorting of cells with different labeling intensities following stimulation by antigen, which might also provide clones useful for their cellular or humoral specificities. Sorting experiments along this line should also be able to determine to what extent late proliferative responses in antigen-stimulated cells are the result of recruitment, rather than of specific reaction to antigen.

A look at Figure 7-23, however, shows that the fluorescence distributions calculated by the model for successive generations of PKH26-labeled cells are rather broad and overlap considerably, meaning that sorting from any particular segment of the distribution would be likely to yield a mixture of cells from several generations. Since the previous edition of this book appeared, **carboxyfluorescein succinimidyl ester (CFSE)**<sup>2349,50</sup> has become widely used as a tracking dye for analysis of cell proliferation.

CFSE is, as Dick Haugland points out in the *Molecular Probes Handbook*<sup>2332</sup>, an inappropriate term to describe the succinimidyl ester of 5(6)-carboxyfluorescein diacetate. He suggests CFDA SE; the name may not sell, but the sales receipts from the chemical itself should salve any wounds to his pride. CFSE is not properly a membrane label; it, like FDA and the esters of carboxyfluorescein and calcein, readily crosses cell membranes and enters cells, and is cleaved by intracellular esterases to a fluorescent form. Unlike fluorescein, carboxyfluorescein, and calcein, the fluorescent form of CFSE carries a reactive succinimidyl group, allowing it to bind covalently to amino groups in proteins; this accounts for the extremely long-term retention of the dye.

Both CFSE and the PKH dyes have been reported to be toxic to cells; this limits the concentrations at which they can be used to label a first generation, and, since tenth-generation cells will, on average, be only 1/1024 as bright as first generation cells, starting with lower concentrations of tracking dyes will usually decrease the number of generations discernible by flow cytometric measurements.

The PKH dyes and other long-chain fatty acid derivatives are more difficult to load into cells than is CFSE, but it is possible to make measurements of fluorescein- and PE-Cy5-labeled antibodies in cells stained with PKH26, while it is impossible to use fluorescein-labeled antibodies and difficult to use PE and some of its tandems in CFSE-stained cells. However, as can be seen from a comparison of Figures 7-23 and 7-24, CFSE clearly outdoes PKH26 in delineating generations. It is likely that if cells were sorted from a narrow middle region of one of the peaks shown in the bottom panel of Figure 7-24, the sorted population would come predominantly from a single generation.

Tracking dyes have had a substantial impact on studies of cellular immunology in recent years, and their applications to the study of lymphocyte development and activation will be discussed further in Chapter 10 (p. 501).

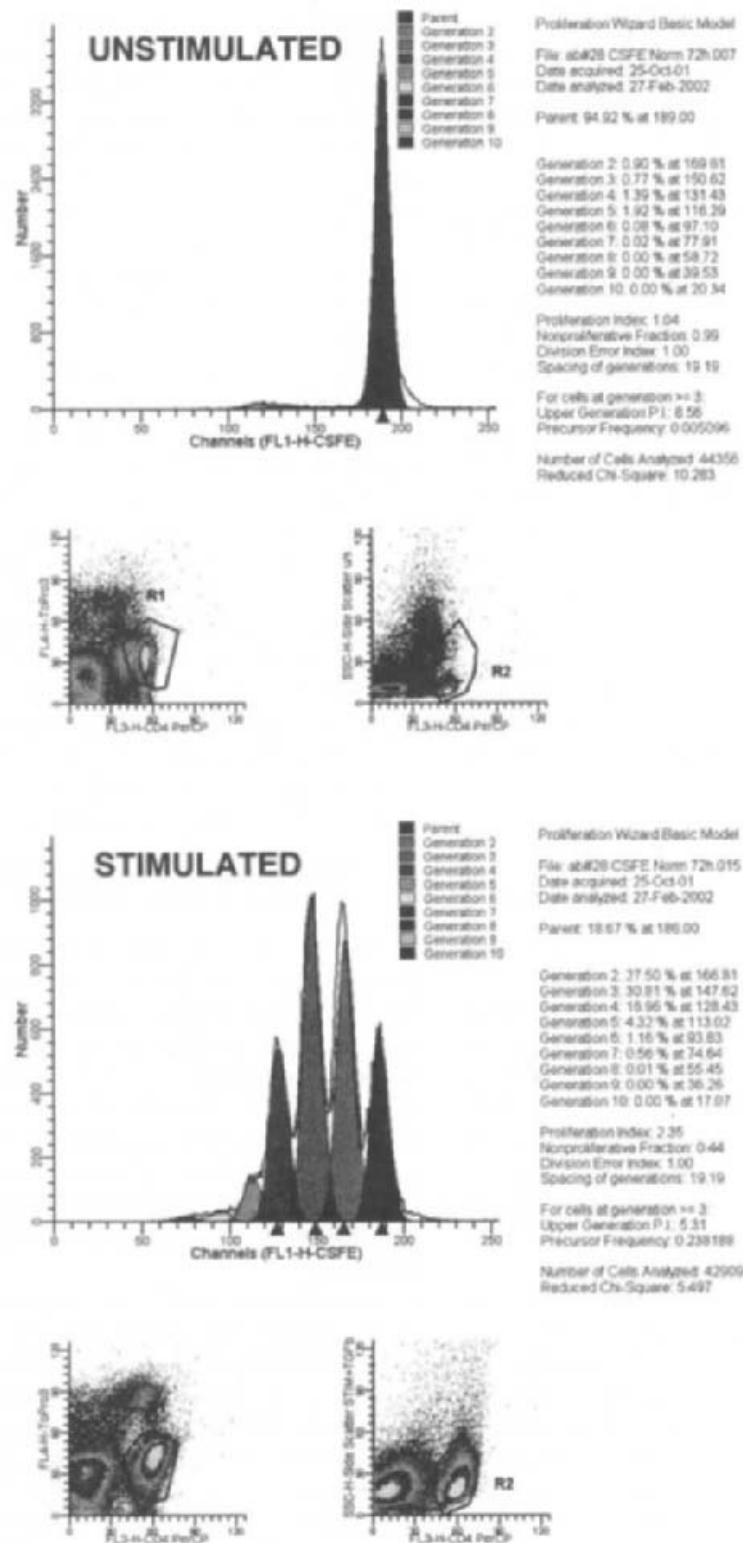

Figure 7-24. Cell proliferation of CD4<sup>+</sup> lymphocytes indicated by dilution of fluorescence of carboxyfluorescein introduced into cells as the succinimidyl ester of carboxyfluorescein diacetate (CFSE). TO-PRO-3 was used to exclude dead cells. The data and figures were provided by Jonni Moore (U. of Pennsylvania) and Don Herbert (Verity Software House).

It would be desirable to have a tracking dye that did not emit fluorescence in the range of major popular antibody labels. There is nothing magic about the chromophores of either the PKH dyes or CFSE. The critical components of a PKH dye or of DiO, DiI, etc. are the long chain alkyl groups, which lock the compound into the lipid bilayer; the cyanine dye serves as a label. The chromophore in PKH26 is basically Cy3; Molecular Probes offers similar dyes with C<sub>18</sub> alkyl groups and red-excited (Cy5-like) or near-infrared-excited (Cy7-like) chromophores.

The key characteristics of a CFSE-like dye are permeancy and a reactive group (amine-reactive, in the case of CFSE). Molecular probes sells a succinimidyl ester of SNARF-1 carboxylic acid, acetate, this compound, for which I'll accept any nickname with fewer than 10 letters, can be excited at 488 nm, but emits at longer wavelengths than does CFSE. Unfortunately, SNARF-1 itself was designed as a pH indicator; its emission characteristics change rather more dramatically with pH than do those of fluorescein, and any changes in intracellular pH with cell cycle stage or generation number might compromise the use of the SNARF-1 derivative for proliferation studies. A permeant reactive dye with spectral characteristics similar to Cy5.5 or rhodamine 800 (red-excited, emission >690 nm) would permit use of fluorescein, PE and almost all PE tandems for antibody labeling and gating, and could be very useful.

## Membrane Organization and Fluidity/Viscosity

### Lipid Packing Assessed with Merocyanine 540

**Merocyanine 540 (MC540)** is a green-excited, orange-fluorescent dye that, when it is applied to nerve axons, exhibits very small (0.3%) fluorescence changes in response to changes in membrane potential<sup>457</sup>. It can be excited at 488 nm, and its fluorescence is detectable through the 575 nm filters normally used for phycoerythrin measurement. MC540 was found by Valinsky, Easton, and Reich<sup>467</sup> to stain immature and leukemic but not normal leukocytes; the staining was independent of membrane potential. The dye was subsequently used to photosensitize leukemic<sup>1556</sup> and malaria-infected<sup>1557</sup> cells.

McIlvoy et al<sup>1558</sup> noted that MC540 binds preferentially to membranes with loosely packed lipids, and provides a flow cytometric method for assessing lipid organization in individual cells. Analyses of cells stained simultaneously with MC540 and 1-[4-trimethylammoniumphenyl]-6-phenyl-1,3,5-hexatriene, which gave a signal to normalize for surface area, showed that all leukocytes in peripheral blood bound equivalent amounts of dye per unit surface area, indicating that lipids of the plasma membranes of all cell types are organized similarly. Lymphocytes, monocytes, and neutrophils activated by appropriate stimuli all bound increased amounts of dye per unit surface area, indicating a change in lipid organization to a less-ordered state.

Bright staining with MC540 is often achieved by UV illumination of the cells during staining. Szabo et al<sup>1559</sup>

showed that staining of mouse spleen cells was greatly enhanced by UV illumination before addition of the dye, and that UV treatment caused an increased permeability toward propidium iodide and, later, intracellular fluorescein as well as increased MC540 staining, although the increase in MC540 fluorescence preceded the other effects. They suggested that penetration of MC540 to the more fluid inner membrane structures explains the fluorescence increase.

Double-staining experiments by Belloc et al<sup>1560</sup>, using MC540 and Hoechst 33342 on total bone marrow or peripheral blood cells, confirmed that the MC540-stained population included all the cycling cells, indicating that MC540 can be used as a marker for human hemopoietic cells. However, Pyatt<sup>2736</sup> et al found more total and committed progenitor cells in the CD34+MC540 dim population than in the CD34+MC540 bright population.

Around the time Annexin V<sup>2353,4</sup> was recognized as detecting membrane asymmetry in apoptotic cells, it was reported that MC540 was also effective for that purpose<sup>2737-8,2910</sup>, staining apoptotic cells more brightly. The dye has been used only sporadically to detect apoptosis, but appears to be effective<sup>2739,40</sup>. Changes in MC540 fluorescence occur during platelet activation, and are apparently dependent on changes in accessibility of phosphatidylserine<sup>2741,2</sup>.

I suspect that at least some oxonol dyes may also respond to membrane asymmetry; I will have more to say about this in the section on membrane potential dyes.

### Membrane Fluidity and Microviscosity: Assessment Using Fluorescence Polarization

The concepts of **membrane fluidity** and **microviscosity** date from the early 1970's<sup>397-8</sup>, by which time the Singer-Nicholson **fluid mosaic model of the cell membrane**<sup>399</sup> was generally appreciated, if not equally generally accepted. While it had become clear that many of the processes involved in the regulation of cell growth, differentiation, and differentiated function were mediated by receptor proteins extending through the cell membrane, it was also evident that the function of these proteins might be altered by local or global changes in the state of the **lipid bilayer** portion of the membrane.

Shinitzky and Inbar<sup>197-8</sup> investigated this possibility using measurements of the polarization of fluorescence of a hydrophobic probe bound to the membrane bilayer to derive an estimate of the physical state of membrane lipids. As was noted on pp. 114 and 283, when fluorescence is excited by polarized light, both the **polarization** and the **anisotropy** of fluorescence increase as the motion of chromophores becomes more restricted, i.e., as the "viscosity" of the medium increases, or as the "fluidity" decreases<sup>400</sup>.

The probe Shinitzky and Inbar used for their measurements is **1,6-diphenyl-1,3,5-hexatriene (DPH)**. This is an uncharged hydrophobic material that is essentially nonfluorescent when coerced into aqueous media but which exhibits UV-excited blue fluorescence in nonpolar solvents. When a small amount of DPH in tetrahydrofuran (THF) or di-

methyl sulfoxide (DMSO) is added to a cell suspension, examination of cells under the fluorescence microscope shows DPH in most membranous and lipid-containing structures, inside the cells as well as in the outer membrane. If you look at cells such as peripheral blood lymphocytes, in which there aren't a lot of intracellular membranous structures, you'll get the idea that DPH is only in the outer membrane, but it ain't so.

The original measurements of DPH fluorescence polarization were done on cuvettes full of cells in a modified spectrofluorometer; an instrument specially designed for such measurements was later manufactured by Elscint (Haifa, Israel). Differences in anisotropy were found between normal and leukemic cells<sup>401,2</sup>, and between cells before and after exposure to mitogens<sup>403</sup> and viruses<sup>404,5</sup>. These findings stimulated Arndt-Jovin et al to implement anisotropy measurements on their cell sorter<sup>400,406</sup>; they found changes in anisotropy during DMSO-induced differentiation of Friend leukemia cells.

Several factors that affect membrane microviscosity have now been identified. The cholesterol content and the fractions of unsaturated and saturated fatty acids in membrane lipids exert strong influences; cholesterol depletion decreases viscosity while increasing cholesterol content has the opposite effect. Increasing the content of unsaturated fatty acids decreases microviscosity<sup>398</sup>. Changes in lipid composition could explain some of the slower changes in microviscosity observed in connection with interactions of various materials with the membrane; however, it is more difficult to explain rapid changes in microviscosity on this basis.

In experiments with phospholipid membrane vesicles, Lelkes<sup>411</sup> showed that measured microviscosity increases with the electrical potential difference across the cell membrane, whether the interior of the vesicles is made electrically negative with respect to the exterior (as is the case with cells) or vice versa. He suggested that this results from an electrostrictive effect, i.e., that the high electric field, proportional to the transmembrane potential difference, which exists only across the thickness of the membrane bilayer maintains orientation of the lipid molecules and that mobility is decreased as field strength increases.

Karnovsky et al<sup>412</sup> have attacked the concept of membrane microviscosity as being too simplistic; they have amassed abundant evidence that the mobility of lipids differs in different domains of the membranes of individual cells. One certainly cannot expect to derive detailed information from measurements of the average anisotropy of a few million cells in a cuvette. This doesn't mean that there may not be a place for flow cytometric measurements of DPH emission anisotropy in single cells, but nobody seems to have found a good use for them yet. Later studies, which have looked at fluorescence polarization using DPH<sup>845</sup> and other membrane probes<sup>413,846</sup> have not provided a major impetus for a resurrection in this area.

Details of flow cytometric measurement techniques have been given by Fox and Delohery<sup>845</sup>, and, more recently, by

Bock et al<sup>1561,2</sup> and Collins and Grogan<sup>1563,1032</sup>. Collins and Grogan<sup>1563</sup> compared bulk fluorometric and flow cytometric measurements and found them equivalent; they also<sup>1564</sup> examined a series of *n*-(9-anthroyloxy) fatty acid probes, where *n* = 2, 3, 6, 7, 9, 12, and 16, showing that the anthroyloxy moieties of the probes located at a graded series of depths in the outer leaflet of the plasma membrane of living HeLa cells. For different *n*, the efficiency of quenching with an aqueous phase quencher, Cu<sup>2+</sup>, decreased with increasing *n*. The probes should therefore be usable for measurements of dynamic parameters related to membrane fluidity at different depths in the plasma membrane. Vincent-Genod et al<sup>2762</sup> noted a decrease of 3-, 6-, and 9-(9-anthroyloxy) fluorescence anisotropy values in late apoptotic lymphocytes, compared to viable lymphocytes.

Seidl et al<sup>2518</sup> devised a method for estimating membrane microviscosity that does not require fluorescence polarization measurements. Pyrene decanoic acid (PDA), a UV-excited lipid probe, normally emits at 397 nm; collision between two molecules, one in the excited state and one in the ground state, forms an excimer that emits at 485 nm. Since the rate of excimer formation depends on the rate of diffusion of molecules in the membrane, a change in microviscosity results in a change of the excimer/monomer fluorescence emission ratio.

### Lipid Peroxidation

Hedley and Chow<sup>1565</sup> described a method for measuring lipid peroxidation using time resolved flow cytometry. The naturally fluorescent fatty acid *cis*-parinaric acid, which is readily consumed in lipid peroxidation reactions, losing its fluorescence, was loaded into cells by exposure to a 5  $\mu$ M concentration for 60 minutes at 37 °C. Fluorescence microscopy showed diffuse staining of surface and internal membranes. A 325 nm HeCd laser was used to excite parinaric acid fluorescence at 405 nm. Addition of the oxidant *t*-butyl hydroperoxide resulted in a burst of intracellular oxidation, demonstrated by simultaneously loading the cells with dichlorofluorescein, and in loss of parinaric acid fluorescence over time; this was followed by cell death, indicated by decreased forward light scatter and propidium uptake. Pretreatment of the cells with the antioxidant  $\alpha$ -tocopherol (200  $\mu$ M) reduced the rate of loss of parinaric acid fluorescence and delayed the onset of cell death. Simultaneous biochemical analysis of the lipid peroxidation breakdown product malondialdehyde revealed a close temporal correlation with loss of parinaric acid fluorescence, with and without  $\alpha$ -tocopherol treatment, suggesting that the flow cytometric assay for lipid peroxidation is comparable to standard methods.

The problem with parinaric acid is that, while it is very well excited by a 325 nm He-Cd laser, it is very poorly excited at 350 nm and above, meaning that you will get almost no signal out of the probe even if you use a big argon or krypton laser for UV excitation. That didn't stop somebody I knew from publishing some essentially meaningless figures

in which the distributions (mostly of noise) just happened to shift around in the right directions to support his hypothesis – and in a good single-name journal, too. As I have said before, bad flow happens to good journals.

If you only have a 488 nm laser, you can measure lipid peroxidation using a fluorescence emission ratio from hexadecanoyl-BODIPY-FL<sup>2743</sup>, or by measuring decreasing fluorescence from 5-dodecanoylfluorescein<sup>2744,5</sup> or fluoresceinated phosphatidylethanolamine<sup>2746,7</sup>.

### Membrane Permeability to Dyes and Drugs: The Drug Efflux Pump(s) Revisited

Differences in the temporal pattern of uptake and retention of Hoechst 33342 were used in the late 1970's for studies of lymphocyte activation<sup>248,50,253,257</sup>; this led to the demonstration in 1981 by Lalande, Ling, and Miller that dye retention was determined by the operation of what is now recognized as the P-glycoprotein (Pgp) drug efflux pump. This subject has already been discussed briefly on p. 309; we will return to it presently.

Flow cytometry of the kinetics of intracellular accumulation of fluorescent drugs, e.g., anthracyclines such as doxorubicin (daunomycin) and adriamycin<sup>352,3,814</sup>, and drug analogues, such as fluoresceinated derivatives of methotrexate<sup>354,6</sup>, can obviously be useful in pharmacology, e.g., for determination of mechanisms of drug resistance. The methotrexate analogues, in particular, have been valuable in studies of gene amplification<sup>357</sup>. Krishan, who has done extensive studies of anthracycline uptake and retention patterns in tumor cells and of their perturbation by phenothiazines and calcium channel blockers<sup>352,815-7</sup>, has reviewed the general area of flow cytometric analysis of drugs and drug analogues on several occasions over the years<sup>818,2748-50</sup>.

The cationic dye rhodamine 123 had been shown by Lan Bo Chen and his colleagues in 1980 to stain mitochondria<sup>489</sup>; it was established in 1981 that the retention of the dye in mitochondria after washing was dependent on the existence of an interior-negative mitochondrial membrane potential<sup>490</sup>. By this time, it had already been noted that lymphocyte stimulation was accompanied by increased rhodamine 123 staining<sup>493</sup>. From 1981 to 1985, rhodamine 123 retention was thought to depend primarily on membrane potential. In 1985, Sonka et al<sup>1566</sup> found that in cells of an anthracycline-resistant tumor line, which was known to have an active efflux pump, rhodamine 123 retention was low. Substances such as verapamil, which were known to increase the sensitivity of anthracycline-resistant cells, inhibiting the pump, also shifted the cells from low to high rhodamine 123 retention. Tapiero et al<sup>1567</sup> reported similar findings in 1986.

At about the same time, Bertoncello, Hodgson, and Bradley<sup>1568</sup> and, slightly later, Mulder and Visser<sup>1569</sup> observed that bone marrow stem cells exhibited low rhodamine 123 retention. This characteristic remains useful for isolation of cells with marrow repopulating activity; it is now known to be due to the operation of an efflux pump, although it was originally attributed to decreased mitochondrial respiration.

Since the mid-1980's, various authors have described methods for demonstrating multidrug resistance, i.e., the presence and activity of the drug efflux pump, in tumor cells, based on uptake and or retention of Hoechst 33342<sup>1570</sup>, anthracyclines<sup>1571-3, 1576</sup>, rhodamine 123<sup>1575, 1577</sup>, cyanine dyes<sup>1577</sup>, and antibodies against P-glycoprotein<sup>1573-4, 1576</sup>. The pump has also been demonstrated in human peripheral lymphoid cells (B and NK, but not most T cells)<sup>1578</sup>, trypanosomes<sup>1579,80</sup>, and some bacteria<sup>1581-2</sup>. Kessel et al<sup>1577</sup>, in an article well worth reading, demonstrated efflux from drug resistant cells of Hoechst 33342, rhodamine 123, and several cyanine dyes commonly used as membrane potential probes, and cautioned against drawing the conclusion that changes in rhodamine and cyanine dye fluorescence in cells are due to membrane potential changes. Oxonol dye probes of membrane potential, which are anionic and which apparently do not enter cells in large amounts, are largely unaffected by the operation of the pump. I will return to this issue in the discussion of membrane potential probes.

Assaraf and others<sup>1583-5</sup> further characterized methotrexate (MTX) resistance mechanisms, demonstrating that fluorescein-MTX is not transported by the carrier responsible for MTX uptake, but enters cells by passive diffusion. The labeled compound, however, remains useful for demonstration of increased intracellular dihydrofolate reductase, which causes one type of resistance to MTX. A second type appears to be due to decreased transport of MTX analogues into cells.

Fluorescent probes for specific transporters have been developed; Wiley et al<sup>1586</sup> described a fluorescein-labeled probe for the nucleoside transporter, while Knaus et al<sup>1587,8</sup> made BODIPY-labeled probes which bind to calcium channels. Using a somewhat less specific probe, the blue-violet-excited, green fluorescent anionic dye lucifer yellow, loaded into cells by electroporation, Dinchuk et al<sup>1589</sup> showed that an anion transport mechanism was responsible for efflux of the dye from lymphocytes. Aller et al<sup>2751</sup> and Natarajan and Srienc<sup>2752-3</sup>, respectively, used NBD-glucose to study glucose uptake kinetics in rat brain cells and *E. coli*.

Dordal et al<sup>2754</sup> used a three-compartment mathematical model and kinetic measurements to assess the pharmacokinetics of doxorubicin.

We now know that there are multiple pumps that can mediate efflux of drugs and dyes from cells<sup>2748-50</sup>. In addition to P-glycoprotein, there are (at least) multidrug resistance protein (MRP)<sup>2755-7</sup>, breast cancer resistance protein (BCRP)<sup>2758</sup>, and lung resistance protein (LRP)<sup>2748</sup>, and some tumors and cell lines contain more than one active pump. Whole-cell studies of one pump in such cells therefore require either the use of a substrate that is processed by only that pump or the use of a selective inhibitor(s) for the pump(s) not under study.

P-glycoprotein transports Hoechst 33342, rhodamine 123, and doxorubicin, among other compounds, and many acetoxymethyl (AM) esters, including indo-1 AM and fluo-3 AM, both used for cytoplasmic calcium measurements, and

**calcein AM**, used in tests of membrane integrity (pp. 370-1). If you are using these probes, it is advisable to determine whether or not the cells you are studying contain pumps that might interfere with your experiment. P-glycoprotein is inhibited by **cyclosporin A**, which competes with substrate molecules for binding sites, by the calcium channel blocker **verapamil**, which does not, by phenothiazines such as **trifluoperazine** and **prochlorperazine**, and, for those with a taste for political controversy, by **RU 486**.

MRP is a particularly effective transporter of glutathione S-conjugates of drugs; it also effluxes both **calcein AM** and free **calcein**, and carboxy-2',7'-dichlorofluorescein<sup>2756</sup>, but not BCECF-AM<sup>2757</sup>. MRP is inhibited by **indomethacin**, **MK571**, and **probenecid**. **Mitoxantrone** was found by Minderman et al<sup>2758</sup> to be the only material that served as a substrate for BCRP in all of the cell lines they tested; fumitremorgin C inhibited mitoxantrone efflux by BCRP.

It is advisable to use antibodies<sup>2755,2759</sup>, particularly antibodies that do not interfere with pump activity, as well as substrates to detect and quantitate protein pumps. Chen and Simon<sup>2760</sup> transfected cells with a Pgp-GFP fusion protein, allowing simultaneous quantitation of cells' content of protein and substrate, and showed that the degree of efflux depended only on the quantity of Pgp present in cells; Wang et al<sup>2761</sup> have standardized a flow cytometric assay for identification and evaluation of Pgp inhibitors.

There is a great deal more biochemical diversity among the prokaryotes than among the mammals, and we know that bacteria have a broader range of pumps than we do, and use some them to resist the actions of antibiotics. This is probably a good place to point out that all membranes are not created equal; the outer membrane of **Gram-negative bacteria** is, under normal conditions, impermeable to many lipophilic materials, such as cyanine dyes, which readily and rapidly enter almost all other types of cells, although it can be permeabilized, e.g., with EDTA. I have used this property as the basis of a "flow cytometric Gram stain" which will be discussed in Chapter 10; Molecular Probes advertises sets of nucleic acid dyes for the same purpose.

### Endocytosis of Macromolecules and Particles

Fluorescently tagged macromolecules<sup>368-70</sup>, plastic microparticles<sup>371-3</sup>, and bacteria<sup>374-5</sup> have been used to study **endocytosis** and **phagocytosis**. Murphy et al<sup>369</sup> and Bassøe et al<sup>375</sup> have examined pH changes in the environment of endocytosed material, utilizing the pH-dependence of fluorescein fluorescence<sup>202,4</sup>. A refinement in this technique was introduced by Murphy et al<sup>376</sup>; cells are incubated with a mixture of fluorescein- and rhodamine B-labeled ligands, and excited at 488 nm, and the ratio of fluorescein and rhodamine fluorescence is calculated.

The emission intensity of fluorescein, when the dye is excited at 488 nm, decreases with decreasing pH over the range 8-4. The spectrum of rhodamine B does not change appreciably with pH over this range. The ratio of fluorescence signals from the two labels can thus be used to provide

a measure of the ambient pH that does not vary with variations in the total amount of material in different cells. Additional material relating to this technique will appear in the later section on pH measurements.

As one would expect, work on flow cytometric measurement of endocytosis has concentrated heavily on analysis of blood mononuclear and polymorphonuclear phagocytic cells. Terstappen et al<sup>825</sup> developed a flow cytometric assay for circulating immune complexes in serum based upon phagocytosis of the complexes by granulocytes from healthy donors and subsequent immunofluorescent detection of intracellular complexes. Davis et al<sup>826</sup> have used fluorescein-labeled dextran to study fluid pinocytosis induced in polymorphonuclear cells by chemotactic peptides.

When microparticles, rather than macromolecules, are used to demonstrate endocytosis, it is possible to precisely specify both the size and spectral characteristics of the indicator used, and, if one cares, to obtain histograms of the numbers of particles taken up by cells, provided the particles are relatively bright and uniform. The particles themselves may also be coated with specific ligands. To permit simultaneous immunofluorescence analysis using fluorescein antibodies and measurement of phagocytosis, Rolland et al<sup>827</sup> employed 0.3  $\mu\text{m}$  plastic particles labeled with ethidium as targets; the red fluorescence of the particles could readily be discriminated from fluorescein fluorescence.

Newer phagocytosis assays have added extra tricks. Using two-color analysis, orange- or red-labeled bacteria, and **2,7-dichlorofluorescein diacetate (DCFH-DA)**, an indicator of oxidative metabolism which will be further discussed shortly, it is possible to determine both phagocytosis and the subsequent occurrence of the respiratory burst<sup>1590,1</sup>; approximately the same trick can be done using green-labeled bacteria and **hydroethidine**, a derivative of ethidium that is oxidized to the red fluorescent form during the respiratory burst<sup>1592</sup>. Phagocytosis can also be assayed, with somewhat less certainty, with DCFH-DA and unlabeled bacteria, using the occurrence of the burst as an indicator of phagocytosis<sup>1593</sup>. Phagocytosis of immunoglobulin-coated sheep erythrocytes and respiratory burst can be assayed using the fluorescent product of DCFH-DA for the latter and changes in scatter signals for the former<sup>1594</sup>.

Differentiating between green-labeled phagocytic targets attached to the cell surface or in solution and those that have actually been ingested can be accomplished by adding trypan blue<sup>1595</sup> or crystal violet<sup>1596</sup> to the sample. A somewhat more informative technique allows neutrophils to phagocytose fluorescein-labeled, heat-killed yeast cells, after which ethidium bromide is added to the solution. Ingested yeast cells are green; those attached to the cell surface are red<sup>1597</sup>. Similar distinctions can be made by allowing cells to ingest opsonized green fluorescent beads and then adding red fluorescent antibodies to stain the externally bound, but not the ingested beads<sup>1598</sup>; this requires lots of fluorescence compensation, and would probably work better with red beads and green antibodies. If all you want to measure is the ingested

labeled bacteria, a commercial lysing reagent can be used to get rid of the rest<sup>1593</sup>.

Ma et al<sup>1600</sup> used crystal violet to quench fluorescence from antibody in solution, which allowed them to demonstrate internalization of fluorescein-conjugated IgG from normal serum or serum containing anti-ribonucleoprotein by normal lymphocytes. The results showed that 54% of normal lymphocytes were penetrated by anti-RNP antibody and 23% by normal IgG, respectively. Suzuki et al<sup>1601</sup> employed DiI as a label to study endocytosis of lipid microspheres. Haynes et al<sup>1602</sup> studied intracellular digestion of endocytosed albumin by labeling the protein so heavily with rhodamine that the fluorescence of the dye was largely quenched; as protein was hydrolyzed within phagocytic vacuoles, small rhodamine-labeled fragments were released into solution, and became more fluorescent.

Wang Yang et al<sup>1603</sup> used pulse width and area measurements to analyze capping and endocytosis of fluorescein-immunoglobulin by mouse B cells; fluorescence decreased when the material entered acidic subcellular compartments. Chanh and Alderete<sup>1604</sup>, however, observed decreases in fluorescence intensity associated with capping itself.

Bassøc et al<sup>1605</sup> have recently described the use of multiple probes, flow cytometry, and confocal microscopy to dissect the phagocytic process in neutrophils; they were able to demonstrate formation of reactive oxygen species (ROS) (pp. 379-80) in phagosomes.

Moving away from the mammals, flow cytometry and mathematical modeling have been applied to analysis of feeding by the ciliated protozoan *Tetrahymena pyriformis*<sup>1605,7</sup>. Flow cytometric analysis of the distribution of various types of microplankton before and after exposure to larger organisms has also been used to determine the dietary habits of the latter<sup>1606</sup>. Nature is red in cilium and pseudopod...and if it isn't, we can stain it so it is.

## Enzyme Activity

**Enzyme activity** in single cells can be demonstrated and quantified by flow cytometry following incubation of the cells with **chromogenic** or **fluorogenic substrates**<sup>358</sup>, which, respectively, yield colored and fluorescent products. Some products normally detected by their absorption are fluorescent, so the distinction between chromogenic and fluorogenic substrates can be blurry. The colored reaction products of chromogenic substrates are detected by scatter and absorption or extinction measurements; forward and side scatter as measured in conventional fluorescence flow cytometers are generally usable for this type of analysis. We have already encountered fluorogenic substrates in the contexts of membrane integrity determination (fluorescein diacetate, etc.) and signal amplification (p. 344).

Bayer's instruments for differential leukocyte counting (developed by Technicon, which was acquired by Bayer) measure **peroxidase** activity by scatter and absorption to discriminate among lymphocytes, monocytes, neutrophils, and eosinophils<sup>345</sup>. These systems have also been adapted to

study staining kinetics<sup>348</sup> and, using immunoenzyme staining methods, to analyze T cell subsets in peripheral blood<sup>79,1583</sup>. Ross et al<sup>1609</sup> described a pararosaniline method for esterase staining and a naphthyl phosphate method for alkaline phosphatase staining, allowing the Technicon H-1 to be used for those relatively common cytochemical analyses. Kaplow, who collaborated in this work, had earlier used chromogenic substrates with the Bio/Physics Cytograf, which measured scattering and extinction of 633 nm laser light, to demonstrate esterase, peroxidase, and phosphatase activities in blood cells<sup>359,60</sup>.

Dolbeare and Smith<sup>358</sup> discussed a number of **fluorogenic substrates** that can be used to demonstrate the activity of enzymes in, and in some cases on, cells; many such materials are available commercially. The majority of fluorogenic substrates are derivatives of **fluorescein**, of **coumarins** such as **4-methylumbelliferone (4-MU)**, or of  **$\alpha$ -naphthol**. Substrates derived from fluorescein, as would be expected, yield blue-excited, green fluorescent products, while coumarin and  $\alpha$ -naphthol-based substrates, the latter more often employed as chromogens rather than fluorogens, form products that require UV or violet excitation and emit in the blue and green regions of the spectrum. Derivatives of **resorufin**, which form green- to yellow-excited, orange-red fluorescent products, can be used to demonstrate esterases and oxidative enzymes. The excitation maximum of resorufin, however, is at about 570 nm, necessitating the use of a krypton laser at 568 nm, a dye laser, or, possibly, the 577 nm line of a mercury arc lamp for excitation.

Dolbeare and Vanderlaan<sup>363</sup> and Smith and Dean<sup>364</sup> have described fluorogenic reagents based upon other UV-excited, blue fluorescent and blue-excited, green fluorescent materials for flow cytometric demonstration of peptidases and acid phosphatases. Fluorogenic substrates suitable for use with red excitation are uncommon; Lee, Berry, and Chen<sup>1610</sup> described one candidate, **vita blue**, which could be derivatized for use as both an esterase substrate and a pH indicator, but the dye hasn't made it to the majors yet, as far as I know.

If cells are incubated with two (or more) fluorogenic substrates that yield products with different spectral characteristics, it is possible to demonstrate and monitor several enzymes in cells using multiparameter flow cytometric analysis<sup>364,7</sup>. Since the amount of detectable reaction product in a cell at any given time depends on many factors, including the rate of accumulation of substrate in the cell, the rate of entry of substrate to the cellular compartment containing enzyme, the rate of enzymatic reaction, and the rate of efflux of reaction product from the cell, it is not surprising that cellular fluorescence values, especially for different cell types, do not always correlate with enzyme activities<sup>824</sup>.

Dick Haugland reviewed fluorogenic substrates and their uses in an 8-page article in 1995<sup>2764</sup>; since his current (2002) edition of the *Molecular Probes Handbook*<sup>2332</sup> devotes 56 pages to the subject and probably has at least 8 pages of references, you probably don't need to look for the article. Both article and handbook emphasize the desirability of

trapping the fluorescent product in or on cells for flow cytometry and other assays done on cell suspensions.

### Indicators of Oxidative Metabolism I: Tetrazolium Dye Reduction

Blair et al<sup>820</sup> used forward and side scatter measurements to demonstrate the development of oxidative enzyme activity in HL-60 human promyelocytic leukemia cells stimulated to granulocytic differentiation by dimethyl sulfoxide. The reagent employed was **nitroblue tetrazolium (NBT)**<sup>361</sup>, widely used in histo- and cytochemistry for demonstration of **oxidative enzymes**. NBT, which is colorless, is reduced to a diformazan that forms an amorphous blue-black precipitate. **NBT reduction** is used as an indicator of the function of mature granulocytes and to determine whether morphologically immature cells belong to the myeloid series.

Blair et al found that the forward scatter signal was decreased, and the orthogonal light scatter signal was increased, in cells that reduced NBT. This work was noteworthy because it called attention to a general method for demonstrating color reactions in cells (or at least those which yield products with very high extinction) that requires neither absorption nor extinction measurements, and thus could be used with most flow cytometers.

Huet et al<sup>1611</sup> used side scatter signals for flow cytometric analysis of **3-(4,5-dimethylthiazolyl-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT)** reduction; the color reaction produced when MTT is reduced is commonly used as a viability indicator in cell cultures. Fattorossi et al<sup>1612</sup> devised an alternate method for measurement of tetrazolium dye reduction by neutrophils; the cells were labeled with fluorescein-con A, the fluorescence of which was quenched by the formazan product of NBT reduction. Van Noorden, Dolbeare, and Aten<sup>1613</sup> proposed a more general method for detection of enzymatic reactions yielding colored formazan products; the formazan quenches glutaraldehyde-induced "autofluorescence" in cells.

Fluorescent tetrazolium dyes were investigated by Severin and Stellmach<sup>821,2</sup>, who measured oxidative activity of living cells using **cyanoditoyl tetrazolium chloride (CTC)**, which is reduced to a water-insoluble fluorescent formazan that has an excitation maximum at 450 nm and emits in the range from 580 to 660 nm. CTC generates more product than NBT<sup>1614</sup>; Huang and Severin<sup>1615</sup> used it with lactate, fumarate, and other metabolic intermediates to characterize the activities of six different dehydrogenases in Ehrlich ascites cells, and it has become fairly popular for studies of bacteria<sup>2252</sup>.

### Indicators of Oxidative Metabolism II: 2,7-Dichlorofluorescein Diacetate (DCFH-DA), etc.

Bass et al<sup>362</sup> used another fluorogenic material to demonstrate oxidative metabolism of blood granulocytes. **2,7-dichlorodihydrofluorescein diacetate**, also known as **dichlorofluorescein diacetate (DCFH-DA or H<sub>2</sub>DCFDA)**, like FDA, is uncharged, nonfluorescent, and lipid soluble,

and readily penetrates cells. Nonspecific intracellular esterases transform the ester into a nonfluorescent intermediate, DCFH. In the presence of **peroxidase**, and of H<sub>2</sub>O<sub>2</sub> formed during the **respiratory burst** in activated granulocytes, DCFH is converted to the fluorescent **2,7-dichlorofluorescein (DCF)**. Duque and Ward<sup>821</sup> described the use of DCFH-DA and other dyes for quantitative assessment of neutrophil function. Cells are loaded with 5 μM DCFH-DA for 15 minutes at 37 °C, after which gated fluorescence analysis of the neutrophil population, identified by forward and side scattering characteristics, is done over time following administration of a stimulus such as a phorbol ester. Like fluorescein, DCF does leak out of cells; Molecular Probes offers **carboxy-H<sub>2</sub>DCFDA**<sup>2765</sup>, which responds to the respiratory burst by forming carboxydichlorofluorescein (carboxy-DCF), which is better retained by cells than is DCF<sup>2452</sup>.

DCFH-DA has been used in combination with various particles for combined analyses of phagocytosis and respiratory burst in neutrophils<sup>1590,1,1593-4</sup>. The presence of peroxidase in neutrophils is evidently important for the development of the fluorescent product; monocytes, which have much less peroxidase, don't become as brightly fluorescent as neutrophils, even when H<sub>2</sub>O<sub>2</sub> is added<sup>1616</sup>.

Maresh and Monnat<sup>1618</sup>, studying cells derived from myeloid leukemias, note the existence of a DCFH-DA oxidative pathway stimulated by fluoride, which appears distinct from that involved in the respiratory burst, and wonder whether a similar pathway in normal cells might confound some results obtained with this reagent.

### Indicators of Oxidative Metabolism III: Hydroethidine (Dihydroethidium)

**Dihydroethidium** is probably more widely known under the name **hydroethidine (HE)**, which is a trademark of Prescott Laboratories. It is the product of reduction of ethidium by sodium borohydride; described in 1984 by Gallop et al<sup>973</sup>. The UV-excited, blue fluorescent HE, unlike ethidium, readily enters live cells, in which it may be oxidized to ethidium, which then exhibits its characteristic blue- or green-excited red fluorescence, enhanced by binding to double-stranded nucleic acids. HE has been used as an indicator of viability<sup>1619</sup>; when it is added at low concentrations, little ethidium accumulates in the nuclei of dead cells, while those of live cells become red fluorescent. HE has also been used as an indicator of the neutrophil respiratory burst<sup>1592</sup>; while DCFH-DA responds primarily to **hydrogen peroxide** generation, HE is more affected by **superoxide**, and the two dyes, used separately, allow discrimination of these two types of **reactive oxygen species (ROS)**<sup>1620</sup>.

### Indicators of Oxidative Metabolism IV: Dihydrorhodamine 123

In 1988, Rothe, Oser, and Valet<sup>1622</sup> introduced **dihydrorhodamine 123**, which is oxidized to the green fluorescent cationic dye **rhodamine 123**, to detect the respiratory burst in neutrophils. According to Henderson and Chap-

pell<sup>1623</sup>, rhodamine 123 fluorescence is produced only in cells containing peroxidase, meaning that the dye is relatively insensitive to superoxide production. Dihydrorhodamine is said to provide brighter signals than DCFH-DA.

### Indicators of Oxidative Metabolism V: Detection of Hypoxic Cells

Some of us, e.g., radiobiologists and radiotherapists, are interested in finding cells that aren't getting and/or using their share of oxygen. Hypoxic cells in transplanted tumors and tumor cell spheroids had been distinguished by their pattern of uptake of Hoechst 33342<sup>1624,6</sup>, but attempts were later made to develop more specific markers. Hodgkiss et al<sup>1627,8</sup> prepared 2-nitroimidazole derivatives with coumarin and indolizine chromophores that appeared useful for hypoxic cell detection. A more recent report<sup>2766</sup> utilized 2-nitroimidazole bound to theophylline (NITP). Under hypoxic conditions, this molecule is bioreductively bound to cellular macromolecules; it is then detected using anti-theophylline antibodies.

### Detection of Caspase Activity

**Caspases** (cysteine-aspartic acid specific proteases) are activated by cell death inducing stimuli, and several reagents have been described for detection of caspase activity in apoptotic cells. **PhiPhiLux**<sup>®</sup> fluorogenic caspase substrates<sup>2556,7</sup> with either green or yellow emission, excitable at 488 nm, are available from **OncoImmunin**. Molecular Probes offers UV-excited, blue fluorescent (aminomethylcoumarin-based) and blue-green excited, green fluorescent (rhodamine 110-based) substrates for caspase-8, which is activated early in apoptosis, and caspase-3, which is activated later<sup>2332</sup>. Caspases can also be detected using fluorescent inhibitors. **Benzylloxycarbonyl-valinealanine-aspartic acid-fluoromethyl ketone (zVAD-FMK)** is a potent broad-spectrum inhibitor of caspases that binds irreversibly (covalently) to the enzyme active site and can block apoptosis. **Serologicals Corporation** offers a line of caspase inhibitors (originally Intergen's) usable for cytometry<sup>2769</sup>. **FAM-VAD-FMK** is a carboxyfluorescein (FAM) derivative of zVAD-FMK, and blocks apoptosis<sup>2770</sup>; there are also FAM-labeled inhibitors selective to various degrees for individual caspases, including caspase-3 and caspase-8, and yellow fluorescent sulforhodamine B-labeled (SR) derivatives of zVAD-FMK and of a caspase-3 inhibitor. **Immunochemistry Technologies** is an alternate source. Since pockets of caspase activity may be localized within cells, it may be advantageous to use scanning rather than flow cytometry for studies of caspases in apoptosis<sup>2770,2</sup>.

### Other Enzymes

**Cathepsin L** activity<sup>1633,4</sup> can be measured flow cytometrically in single viable cells by the intracellular cleavage of non-fluorescent (Z-Phe-Arg)2-rhodamine 110 to the green fluorescent monoamide Z-Phe-Arg-rhodamine 110 and rhodamine 110. (Z-Phe-Arg)2-R110 and (Z-Arg-Arg)2-R110 are several hundredfold more selective for cathepsin L than

for cathepsin B, providing sensitivity for the former. Rhodamine-110-based substrates for nonspecific **aminopeptidases** have also been developed<sup>2771</sup>.

For assessment of activities of **lysosomal enzymes**, van Noorden<sup>1635</sup> reports that the best results have been obtained with methods based on naphthol AS-TR derivatives and with methods for the demonstration of protease activity using methoxynaphthylamine derivatives as substrates and 5'-nitrosalicylaldehyde as coupling reagent.

Dive, Workman, and Watson<sup>1636</sup> used flow cytometry to measure the activity of **gamma-glutamyl transpeptidase**, by monitoring the conversion of gamma-glutamyl aminomethylcoumarin to aminomethylcoumarin. This was technically difficult because of the location of the enzyme on the cell exterior, resulting in rapid escape of the product.

Huang et al<sup>1639,40</sup> have developed fluorogenic substrates for **alkaline phosphatase**. Molecular Probes' **ELF-97 phosphate**<sup>2774,5</sup> produces a violet-excited, green-yellow fluorescent insoluble precipitate when cleaved by either alkaline or acid phosphatases; it can be used to demonstrate phosphatases in cells or for enzyme amplification using alkaline phosphatase-tagged antibodies or nucleotide probes (p. 344). This should be a good reagent to use with violet diode lasers.

Meshulam et al<sup>1369</sup> measured **phospholipase A** activation using bis-BODIPY-phosphatidylcholine, which localizes in the inner leaflet of the cell membrane. Sidhu et al<sup>1641</sup> used ethoxyresorufin and scanning laser cytometry to measure the activities of **cytochrome P-4501A1** and **NADPH DT-diaphorase**.

### Detection of Enzymes and Products by Antibodies

Like other proteins, enzymes can be detected in or on cells using antibodies, although antibody reactivity doesn't absolutely indicate enzyme activity.

Tran-Paterson et al<sup>1629</sup> compared levels of the neutral endopeptidase-24.11, also known as the CD10 or CALLA antigen (Common Acute Lymphocytic Leukemia Antigen) on normal granulocytes, leukemic cells, and transfected COS-1 cells, as detected using fluorescent anti-CD10 antibody and by analysis of enzyme activity in cell suspensions; they found good correlation between results obtained by the disparate methods. Milhiet et al<sup>1630</sup> used a fluorescent inhibitor, *N*-[fluoresceinyl]-*N'*-[1-(6-(3-mercapto-2-benzyl-1-oxopropyl) amino-1-hexyl)thiocarbamide (FTI)], for flow cytometric detection of CD10 as an enzyme.

Antibody detection of the products of enzymatic reactions is a more direct indicator of enzyme activity than is antibody detection of the enzyme protein itself. Antibodies to **phosphotyrosine**<sup>1631,2</sup> have been used for flow cytometric quantification of **tyrosine kinase** activity.

### Enzyme Kinetics in Single Cells

By making appropriate timed multiparameter flow cytometric measurements, it is possible, as Dive, Workman, and Watson<sup>813,1637-8</sup> have shown, to characterize intracellular enzyme reactions in considerable detail, determining relevant

parameters of reaction and inhibition kinetics. As is always the case when kinetic measurements are made using flow cytometry, it is necessary to validate the assumption that the time courses of reactions are similar in at least a substantial fraction of the cells in the sample. Scanning laser cytometry can be used to study enzyme kinetics in individual cells over time when this is necessary or desirable<sup>2776-8</sup>.

### Sulfhydryl (Thiol) Groups; Glutathione

**Sulfhydryl** or **thiol** groups in protein, and non-protein thiol compounds such as the tripeptide glutamyl-cysteinyl-glycine, more commonly known as **glutathione**, play an important role in cells' oxidative metabolism. When cells become hypoxic, the sulfhydryl/disulfide ratio increases, and the free radical scavenging properties of thiols are believed to play a pivotal role in increasing the resistance of hypoxic tumor cells to ionizing radiation<sup>332</sup> and to some chemotherapeutic agents. Flow cytometry of glutathione levels, in particular, has acquired new importance because of their relation to drug resistance in cancer cells<sup>801,1116</sup> and the progression of HIV infection<sup>1117-8</sup>.

Olive and Durand<sup>1333-4</sup> examined several maleimide and **bromobimane** derivatives as reagents for determination of cellular thiols. A maleimide derivative of coumarin emits blue fluorescence and can be used with UV excitation; **monobromobimane** (MBB) and didansylcysteine have similar spectral characteristics. **Fluorescein-5-maleimide** penetrates viable cells less well, but excites at 488 nm.

Treumer and Valet<sup>800</sup> and Rice et al<sup>801</sup>, respectively, characterized **o-phthaldialdehyde** (OPT) and **monochlorobimane** (MCB), both of which form UV-excited, blue fluorescent products with reduced glutathione (GSH), as rapid and specific vital stains for this substance. These reagents were used to demonstrate heterogeneity in GSH content in tumor cell populations. O'Connor et al<sup>1649</sup> advocated the use of **mercury orange**, and Poot et al<sup>1650</sup> the use of **chloromethylfluorescein**, both of which can be excited at 488 nm with, respectively, orange and green emission, for glutathione measurement.

While MCB is probably the most specific reagent for glutathione, because its reaction with the peptide is catalyzed by glutathione S-transferase, the form of this enzyme predominant in human cells (GST-pi) is much less effective in catalysis than is the form found in rodents<sup>1651-2</sup>. In 1994, Hedley and Chow<sup>1653</sup> evaluated a wide variety of methods for measurement of glutathione by flow cytometry, concluding that MBB was the reagent of choice for work with human cells. They found that MBB could be adequately excited by the 325 nm line of a He-Cd laser; its absorption maximum is 394 nm, making a violet diode laser a near ideal source for exciting the probe. MBB emission can be measured adequately at 450 nm; the emission maximum is at 490 nm, but one would normally want to cut off detection well below this wavelength to avoid interference from 488 nm laser light. Mercury orange was found usable, although results were less consistent and background fluorescence was higher.

Chow and Hedley<sup>2779</sup> have measured GSH in clinical samples, attempting to correlate GSH concentration and drug resistance. MBB staining of intracellular glutathione is illustrated in Figure 7-25.

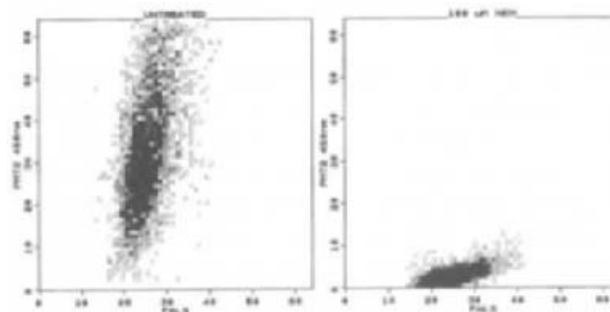

Figure 7-25. Specific staining of glutathione in cells by monobromobimane (MBB). The x-axis shows forward scatter, the y-axis MBB fluorescence, which is greatly reduced in the sample shown in the right panel, which was treated with N-ethylmaleimide (NEM) to deplete intracellular glutathione. The figure was provided by David Hedley (Princess Margaret Hospital, Toronto).

## 7.13 FUNCTIONAL PROBES II: INDICATORS OF CELL ACTIVATION

### Introduction

The functional parameters I will emphasize in this section, i.e., “**structuredness of cytoplasmic matrix**” (SCM), **cytoplasmic and mitochondrial membrane potential**, “**membrane-bound**” and **cytoplasmic calcium ion concentration**, and **intracellular pH**, and the effects of cell surface ligand-receptor interactions on these parameters, have been the subject of a good deal of research and a large number of publications.

Much of the earlier work, and of the earlier literature, did not deal with flow cytometry or with alternative methods of analysis of functional parameters in single cells. Most investigators now working in this area are well aware of the capabilities of flow cytometry, and are in possession of at least some of the information that has already been gained from flow cytometric studies of functional parameters and of the probes used for their measurement.

Cytoplasmic calcium ion concentration ( $[Ca^{2+}]$ ) and distribution, intracellular pH, and membrane potential ( $\Delta\Psi$ ) have all been observed to change during the early stages of **surface receptor-mediated activation processes** related to the development, differentiated function, and pathology of a large number of cell types. Accordingly,  $[Ca^{2+}]$ , pH, and  $\Delta\Psi$  have, individually and collectively, been envisioned as “**second messengers**” mediating responses to cell surface ligand-receptor interactions.

The investigation of changes in the cellular ionic environment during activation has been actively pursued in

hopes of clarifying the mechanisms of receptor function and of developing more precise tests of cell function for clinical and research use. Studies in this area have been facilitated by the development of fluorescent probes that allow estimation of  $[Ca^{2+}]$ , pH, and  $\Delta\Psi$  in cell populations and, in conjunction with instrumental methods such as flow cytometry, in individual cells.

While the current state of the art appears to allow fairly precise quantitation of  $[Ca^{2+}]$ , pH, and  $\Delta\Psi$  in terms of population averages, the use of flow cytometry to measure the same probes in single cells can reveal and has revealed marked heterogeneity even within supposedly homogeneous cell populations. Flow cytometric analysis of the effects of ligands, agonists, and antagonists on individual cells may yield otherwise unobtainable information about mechanisms of receptor function. It can also provide considerable insight into the sources of inaccuracy in measurements based on existing fluorescent probe technology.

### Changes in the Cellular Ionic Environment Following Activation by Ligand Interaction With Cell Surface Receptors

In 1977, when I got interested in this subject, I read a then current review by Sonenberg and Schneider<sup>421</sup> dealing with physical and chemical changes in receptors, in the membrane, and in other cellular structures following ligand interactions with cell surface receptors. Few of the details had been worked out back then (for example, we didn't know JAK about kinases, and NO way did we suspect that a gas could act as a messenger), but the review and a few other articles written in that era did have the big picture:

The earliest detectable biochemical changes occur in milliseconds to seconds after the number of occupied receptor sites increases following exposure of cells to ligand. They include alterations in transmembrane ion fluxes, in intracellular  $[Ca^{2+}]$ , pH, and  $\Delta\Psi$ , and in activities of membrane-associated enzymes such as adenylate cyclase, protein kinases, and phospholipid methyltransferases<sup>422</sup>.

Within seconds to minutes, there may be changes in cyclic nucleotide concentrations, increased protein phosphorylation, and alterations of membrane uptake of sugars, amino acids, and fatty acids.  $Ca^{2+}$  redistributions within the cell and changes in the mobility of membrane lipids and proteins also may occur in this time frame. The biologic response to surface stimulation may occur in milliseconds, as happens in nerve impulse transmission, or after days, as in mitogenic activation of lymphocytes.

The observation that changes in  $[Ca^{2+}]$ , pH, and/or  $\Delta\Psi$  occurred early in the course of interaction of many different ligands with cell surface receptors in diverse cell types led to investigation of the role of ionic species in signal transduction between the cell surface and the nucleus and cytoplasmic organelles such as mitochondria. Ion flux changes were observed, and assigned a role in signal transduction, in the activation of lymphocytes<sup>423-7</sup>, platelets<sup>204,428-31</sup>, mast cells<sup>432-5</sup>,

and neutrophils<sup>436-8</sup>, and in growth factor action<sup>439-45</sup>, as well as in many other cell activation processes.

A single pattern of ionic events has been observed in most of the cell activation processes that have been examined to date. Following ligand binding to cell surface receptors, there is a rapid influx of  $Ca^{2+}$ , usually accompanied by release of intracellular "membrane-bound"  $Ca^{2+}$ , and resulting in a transient rise in free cytoplasmic  $[Ca^{2+}]$ , which lasts for a few minutes at most. There is also typically an increase in intracellular pH, resulting from  $Na^+/H^+$  exchange or antiport, which can be inhibited by amiloride. Changes in membrane potential ( $\Delta\Psi$ ), when they are observed, can go either in the direction of depolarization (decrease in transmembrane potential) or hyperpolarization (increase in transmembrane potential), and appear to be due primarily to  $Na^+$  and/or  $K^+$  shifts across the membrane.

In some cases, crosslinking of two or more receptors by a multivalent ligand is required to induce ion flux changes; in others, binding of monovalent ligands to receptors is all that is necessary. When ion flux changes are initiated by crosslinking, bivalent antibodies to the receptor can produce the same effect as the natural ligand, while monovalent fragments cannot<sup>437</sup>. In most cases, materials that induce ion flux changes of the same nature and magnitude as those induced by natural ligands also induce the biologic responses induced by those ligands. For example, the calcium ionophore A23187 is mitogenic for T lymphocytes, induces platelet aggregation, stimulates histamine release from mast cells, etc.<sup>444</sup>.

If one monitors the average  $[Ca^{2+}]$ ,  $\Delta\Psi$ , or pH of millions of cells in a suspension, it is possible to demonstrate dose-response relationships between the amounts of active ligand added and the magnitude of changes observed in the measured parameters. When the same parameters are followed in single cells, a correlation between ligand dose and degree of response may also be observed<sup>362</sup>. However, when the biologic responses of individual cells are examined, the usual pattern of response appears to be all-or-none<sup>194</sup>. Neurons exposed to neurotransmitters either generate a propagated action potential or they do not; lymphocytes either reproduce or do not, and so on.

It is generally accepted that an individual neuron is subject to the excitatory and inhibitory influences of various neurotransmitters, which are secreted by neighboring cells and which act on its dendrites and cell body, raising or lowering its resting membrane potential and, accordingly, changing its firing threshold. The membrane is a locus for summation of excitatory and inhibitory effects.

It is also known that the biologic responses of so-called "non-excitabile" cells, such as lymphocytes, can be modulated by a great variety of cytokines, peptide hormones, neurotransmitters, and other ligands that react with cell surface receptors. It was hypothesized that, if the signals from these ligand-receptor interactions were transduced by ion fluxes across the cell membrane, the membranes of non-excitabile

cells, like those of neurons, might serve as "summing nodes" for excitatory and inhibitory stimuli.

The fact that ionic responses to ligand binding to surface receptors seem, even at the single cell level, to be dose-dependent, while biologic responses tend to be all-or-none, suggested that there might be  $[Ca^{2+}]$  and/or  $\Delta\Psi$  or pH threshold levels that must be reached for biologic responses to occur. Investigation of this possibility would require means to detect and quantify heterogeneity of cell populations with respect to ligand binding,  $[Ca^{2+}]$ ,  $\Delta\Psi$ , pH, and changes in these parameters. Doing this nondestructively should allow one to make serial observations of cells, which could establish relationships between the nature and magnitude of cells' early responses to ligands and the same cells' subsequent biologic behavior.

It seemed to me at the time that cytometry, flow and otherwise, might usefully and profitably be applied to such studies. I knew there existed some fluorescent probe techniques for estimation of  $\Delta\Psi$ ,  $[Ca^{2+}]$ , and pH; and I thought it would be fairly simple to adapt them for use with flow cytometry, and not much harder to answer all of the biological questions raised above. This view, needless to say, was excessively optimistic, for many reasons, some of which I will explain after the upcoming grand tour of functional parameters.

### "Structuredness of Cytoplasmic Matrix" (SCM) and the Cercek Test for Cancer

"Structuredness of cytoplasmic matrix," or SCM<sup>414</sup>, was probably the first functional parameter measured by flow cytometry. The measurement of SCM, like that of membrane fluidity, requires fluorescence polarization measurements. In this case, the fluorescence is emitted by **fluorescein**, produced by the action of nonspecific cellular esterases on **fluorescein diacetate (FDA)**, about which a fair amount has already been said (pp. 24-7, 369-71).

The original work in this area was done, and the term SCM was coined, in the early 1970's by Lea and Boris Cercek<sup>415</sup>, then working in Manchester, England. They measured fluorescein fluorescence polarization in cell suspensions in cuvettes using a modified spectrofluorometer, and, in analyses of synchronized cell cultures, found changes during different phases of the cell cycle. The **fluorescence polarization**, calculated as described on p. 114, was taken as a measure of SCM.

In studies done over a period of several years (summarized in reference 414), the Cerceks found that SCM changed within a few hours after human lymphocytes were exposed to mitogenic lectins or antigens. They also reported that lymphocytes from cancer patients exhibited diminished SCM responses (i.e., smaller changes in polarization after exposure) to the lectin PHA when compared to cells from controls, and that lymphocytes from patients with cancer showed more marked SCM responses after exposure to preparations containing tumor antigens than did cells from controls. These results seemed to promise a rapid method for

cancer diagnosis, and therefore excited considerable interest among cancer researchers and oncologists and in the diagnostics industry.

From about 1975 on, several groups of investigators attempted to duplicate the Cerceks' results with cancer patients, and at least as many failed as succeeded; this led, among other things, to everybody criticizing everybody else's methodology. It therefore seemed logical to try to put things on a more objective basis by making measurements of single cells, which has since been done by microfluorometry<sup>416</sup> as well as by flow cytometry<sup>338,407,9,417,19</sup>. Stewart et al<sup>338</sup> reported differences in the fluorescein polarization responses of lymphocytes from breast cancer patients and controls following exposure to PHA and pooled tumor antigen; their study was designed to exclude observer bias. Hartmann et al<sup>418</sup> noted diminished polarization responses of lymphocytes from cancer patients compared to cells from controls.

On another front, Price et al<sup>417</sup> demonstrated changes in fluorescence polarization of bone marrow cells within a few hours following addition of preparations of (granulocyte) colony stimulating factor and erythropoietin. By sorting cells with the most marked responses, they were able to obtain suspensions enriched in granulocytic or erythrocytic precursors dependent upon which cell growth factor was used as the stimulus. This suggested that changes in SCM, whatever their physicochemical explanation might be, could serve as general indicators of the effect of activators such as mitogens and growth factors on responsive cells.

Udkoff et al<sup>419</sup> analyzed the effects of the concentration of lectin, FDA,  $Ca^{2+}$ , and  $K^+$  on the polarization responses of lymphocytes from normal donors, and found that all of the above might influence the shape of both fluorescence polarization and intensity distributions. To put it in lay terms, sometimes it works and sometimes it doesn't, and, when it doesn't, you can't always tell why (G. Price, R. Miller, L. Kamensky, R. Udkoff, S. Chan, W. Eisert, W. Beisker, H. Steen, L. Scherr, and others, personal communications). I might add that SCM is not the only indicator of cell activation with which this problem has been encountered. This inhibited commercial development of an SCM-based cancer diagnostic test, but left the way open for further investigation and application of the effect.

Meisingset and Steen<sup>420</sup> investigated binding of fluorescein to proteins and lymphocytes, and noted both polarization and spectral changes on binding. Clearly, the rotational mobility of free cytoplasmic fluorescein will be greater than that of fluorescein bound to intracellular macromolecules, and changes in the ratio of free and bound dye will therefore change the polarization measured in a cell or cell suspension. Based upon studies using **time-resolved spectroscopy**, Kinoshita et al<sup>847</sup> concluded that the fraction of bound molecules and the anisotropy produced by binding are the primary determinants of intracellular fluorescein fluorescence anisotropy; they did not suggest a mechanism by which changes might occur in activation. Prospero et al<sup>848</sup> found that various membrane-active agents changed rates of

fluorescein influx and efflux; similar changes during activation might affect SCM by changing the ratio of free to bound dye.

The difficulty of measuring fluorescence polarization by flow cytometry has impeded investigation of the physicochemical basis of SCM response, although work with carefully modified commercial apparatus<sup>1668-9</sup> has established that polarization changes are routinely detectable in activated cells, and that such changes do not occur in the absence of calcium or in the presence of cytochalasin B.

The SCM test has been intensively studied by two Israeli physicists, Mordechai Deutsch and the late Aryeh Weinreb, and their colleagues at several hospitals and research institutions in Israel and elsewhere. Initial success with the SCM test using bulk fluorometry in the 1980's<sup>1670-2</sup> led Deutsch and Weinreb to develop a static cytometer, the Cellscan<sup>1145</sup>, which uses a single photon counting technique (p. 164) to maximize the precision of measurements of fluorescence polarization of fluorescein and other dyes in single cells. A commercial version of this apparatus is available from **Medis Technology**; Deutsch et al have since developed a next generation apparatus, the Individual Cell Scanner<sup>2780</sup>, which also makes high-precision polarization measurements.

Measurement precision is critical for SCM measurements because the largest changes in polarization tend to occur in those cells with the lowest intensity of intracellular fluorescence. The precision of a fluorescence intensity measurement made in a flow cytometer, in which observation time is constant, decreases as intensity decreases because fewer photoelectrons contribute to lower intensity measurements. The polarization values calculated from low intensity fluorescence measurements will also be less precise. The Cellscan and Individual Cell Scanner count a preset number of photons (usually 10,000 or 20,000) in each fluorescence measurement channel, and derive fluorescence intensity values from the time taken to reach the preset photon count; the contributions to variance from photoelectron statistics are therefore the same for both low and high intensity fluorescence measurements.

The polarization of intracellular fluorescein fluorescence in T cells decreases when the cells are exposed to mitogens; the average polarization of mitogen-treated cells is 9.7% lower than that of control cells at 15 min following addition of mitogen, and 13.5% less at 180 min<sup>2781</sup>. The coefficient of variation of the distribution of polarization values, presumably reflecting biologic variation, is large, approximately 75 percent, and, if the measurement technique itself is not highly precise, it may not be possible to distinguish differences between treated and control cells.

We now know a great deal about SCM and changes in SCM. The effect can be demonstrated using carboxyfluorescein<sup>2782</sup> and BCECF<sup>2783</sup> as well as fluorescein. Decreases in polarization, beginning at 40 min after exposure and lasting 24 hr, are induced by the T cell mitogens PHA, Con A, and anti-CD3 antibody, by phorbol esters, and by the calcium ionophore ionomycin, but not by pokeweed mitogen

(PWM), a B cell mitogen<sup>2781,2784</sup>. The effects of ConA can be counteracted by addition of a competing sugar, methyl  $\alpha$ -D-mannopyranoside within 1 hr, but not after 5 hr<sup>2781</sup>. The mitogen-induced decrease in fluorescence polarization is inhibited by inhibitors of energy metabolism (NaN<sub>3</sub>, NaF, KCN, and a proton ionophore), by proton kinase C inhibitors (H7, staurosporin) and by agents that disrupt cytoskeletal microtubules (colchicine, the *Vinca* alkaloid vinblastine) and microfilaments (cytochalasin B)<sup>2781,2785</sup>.

Intracellular fluorescein fluorescence polarization values measured in cells from the Jurkat T-lymphoblastoid line were lower in S and G<sub>1</sub>/M phase cells than in G<sub>0</sub>/G<sub>1</sub> cells<sup>2786</sup>. Fluorescein fluorescence polarization in human lung-derived fibroblasts was decreased by IL 1- $\alpha$  and IL 1- $\beta$ , and by TNF- $\alpha$ ; the effects of these cytokines were inhibited by vinblastine<sup>2787</sup>. Increases in fluorescence polarization in mouse thymocytes and Jurkat cells occur in the early stages of spontaneous apoptosis and of apoptosis occurring in response to treatment with glucocorticoids, Fas ligand, or cancer chemotherapeutic agents; the increase in polarization is unaffected by treatment with caspase-3 inhibitors. The polarization changes in apoptosis appear to be associated with cell dehydration and shrinkage<sup>2788-9</sup>.

In an earlier edition of this book, I suggested that intracellular pH changes related to cell activation might play a part in the SCM response. The excitation spectra of fluorescein, and of carboxyfluorescein and BCECF which can also serve as indicators of SCM response, are pH-sensitive, and changes in cytoplasmic pH occur in at least some cell activation processes, as will be discussed later, and could conceivably affect both the spectrum and the binding of the dye. However, after extensive discussions with Motti Deutsch and Reuven Tirosh, and consideration of recent findings<sup>2780-9</sup>, I am persuaded that the effect is primarily due to changes in the organizational state and mobility of cytoplasmic proteins, and differences in free and bound amounts of different ionic forms of the dye. SCM changes are real; they're just hard to measure, which has given the whole procedure an undeservedly bad reputation.

Reports of clinical trials of the SCM test in cancer diagnosis continue to emerge<sup>2790-8</sup>; it seems to work overall, but is probably not quite sensitive or specific enough to be widely adopted. However, if you look at the data that have been obtained to date with single cell measurements, something very interesting emerges. Two phenomena are observed in the Cercek cancer test that supposedly differentiate between people with cancer and people without cancer. First, T cells from people with cancer don't show as much of a response to mitogens such as con A and phytohemagglutinin (PHA) as do T cells from people without cancer. That's old news; reports of diminished immune response in cancer, e.g., loss of skin reactions to tuberculin and other antigens, go back for generations. What isn't old news, however, is the observation that a substantial fraction, meaning 10 percent and sometimes several times that, of T cells from people with cancer show an SCM response, or evidence of activation, on

exposure to tumor-derived antigens, which have little or no effect on T cells from people without cancer. This suggests that people with cancer either have a greatly expanded clone or clones of antigen-responsive T cells, or that some recruitment phenomenon is occurring in people with cancer but not in normals.

As I hope will be made clear by the end of this book, there are a lot of ways of measuring lymphocyte activation cytometrically, ranging from looking at calcium fluxes in the first few minutes to measuring activation antigens such as CD69 and CD98 (4F2) and cytokine production after 4-8 hours to measuring increased RNA and DNA synthesis after 24 and 36 hours. We also now have tetramers that allow us to identify cells that respond specifically to antigens.

The time course of SCM changes is roughly that of calcium changes; none of the proponents of the SCM test seem to have followed up and found out whether the activated cells go on to express activation antigens and reproduce. The studies done on SCM in blood cell precursors by Price et al<sup>417</sup> offer some encouragement, but we don't have the data for lymphocytes. Assuming that the cells from cancer patients that are activated by tumor antigens are doing what comes naturally for specifically activated lymphocytes, we ought to be able to detect activation by any of the several means just mentioned, all of which are much easier to implement than fluorescence polarization measurements, and most of which can be implemented on commercial flow cytometers. If the Cercek cancer test really works, this could be a big shot in the arm for clinical flow cytometry, because a lot of people will be getting tested every year or two. If the cancer test doesn't work, at least we might learn something about tumor immunology by looking further into patients' T cell responses to antigen.

The Cerceks themselves moved from England to Southern California around 1980, and went to work for Beckman. Shortly after they got there, I helped some folks at Beckman to build a flow cytometer that was supposed to be used for SCM work. The flow cytometer project stopped, and nothing further was heard until 1993, when the Cerceks published three papers<sup>1673-5</sup> describing the isolation of a cancer-associated, SCM-recognition, immunodefense-suppressing, and serine protease-protecting (CRISPP) peptide from the blood plasma of cancer patients. A consensus, synthetic 29 amino acid CRISPP peptide (CRISPPs) has the same cancer SCM-recognition (CR) activity and SCM-response modifying effects as the natural peptides; in other words, if you add it to normal T cells, they behave like T cells from people with cancer. The Cerceks subsequently attempted to determine the genetic origin of the CRISPP peptide<sup>2779</sup>, and reported that CRISPP peptide increased DNA synthesis in cultured hepatocytes, while increasing DNA synthesis at low doses and decreasing DNA synthesis in higher doses when added to PHA-stimulated cultures of human lymphocytes<sup>2800</sup>. Before Beckman and Coulter merged, Coulter looked into the SCM test and decided not to pursue it; it

doesn't look as if Beckman was any more interested in the CRISPP peptides than in the SCM test.

Thus far, neither the Cellscan nor the Individual Cell Scanner seem to have been used to make a multiparameter measurement of fluorescein fluorescence polarization and of another activation-related parameter (e.g., cytoplasmic Ca<sup>2+</sup>, pH, cytoplasmic or mitochondrial membrane potential, early activation antigen expression, or cytokine production), or even to detect phenotypic differences between responding and nonresponding cells. It would be nice to look into all of that. Every couple of years or so, somebody runs across the SCM literature and asks me about measuring fluorescence polarization of fluorescein in lymphocytes using a flow cytometer, and I have to say that my limited experience bears out Motti Deutsch's contention that flow cytometry isn't precise enough to be useful. Lou Kamensky was trying to implement the SCM test using Ortho's flow cytometers in the late 1970's, without much luck, and I convinced him to look for another indicator of activation that might be easier to measure. I proposed membrane potential, which brings me (and you) to the next topic.

## Optical Probes of Cell Membrane Potential ( $\Delta\Psi$ )

### Membrane Potential and Its Physicochemical Bases

**Electrical potential differences** exist across the membranes of most prokaryotic and eukaryotic cells. These potential differences are due in part to the existence of **concentration gradients** of Na<sup>+</sup>, K<sup>+</sup>, and Cl<sup>-</sup> ions across the cell membrane, and in part to the operation of various **electrogenic pumps**.

The potential differences across the cytoplasmic membranes of resting mammalian cells range in magnitude from about 10 to 90 mV, the cell interior being negative with respect to the exterior. There is also a potential difference of 100 mV or more across the membranes of **energized mitochondria**, with the mitochondrial interior negative with respect to the cytosol; this potential is dissipated when **energy metabolism** is inhibited.

In **prokaryotes**, the enzymes responsible for energy metabolism are located on the inner surface of the cytoplasmic membrane, and the potential difference across this membrane, which is typically 100-200 mV, depends largely on energy metabolism.

The resting potential across the cytoplasmic membrane of mammalian cells is frequently estimated from the **Goldman equation**<sup>455</sup>:

$$\Delta\Psi = \frac{RT}{F} \ln \frac{P_K[K^+]_i + P_{Na}[Na^+]_i + P_{Cl}[Cl^-]_o}{P_K[K^+]_o + P_{Na}[Na^+]_o + P_{Cl}[Cl^-]_i}$$

where  $\Delta\Psi$  is the membrane potential, R is the gas constant, T is the temperature in degrees Kelvin, F is the Faraday, [X]<sub>i</sub> is the concentration of X ions inside the cell, [X]<sub>o</sub> is the con-

centration of X ions outside the cell, and  $P_x$  is the permeability of the membrane to X ions.

### $\Delta\Psi$ Measurement Using Microelectrodes

Membrane potentials can be measured directly using **implanted microelectrodes**, but this becomes increasingly difficult as the technique is applied to smaller cells. Changes in  $\Delta\Psi$  in response to ligand-receptor interactions have, however, been detected by such direct measurements. For example, Taki<sup>456</sup> reported that lymphocytes were electrically **depolarized** (i.e., the potential difference across the membrane decreased in magnitude) within 10 minutes following exposure to PHA; depolarization reached a maximum within a few hours, following which **hyperpolarization** (increase in magnitude of the potential difference) occurred over a period of several days. See p. 408 for a follow-up.

### Indirect $\Delta\Psi$ Measurement in Cell Suspensions Using Distributional Probes

Indirect estimates of  $\Delta\Psi$  can be obtained by monitoring the **distribution of radiolabeled lipophilic cationic indicators** (e.g., <sup>3</sup>H-triphenylmethylphosphonium, or TPMP', which was described by Bakeeva et al in 1970<sup>459</sup>) or of **lipophilic cationic dyes**, such as cyanines and safranins, between cells and the suspending medium. Lipophilic indicators are used because this characteristic enables indicator molecules to pass freely through the lipid portion of the membrane; thus, the concentration gradient of an indicator species C' across the membrane is determined by the potential difference across the membrane according to the **Nernst equation**:

$$[C']/[C]_o = e^{-F\Delta\Psi/RT},$$

where the notation is the same as was used previously. A ratio  $[C']/[C]_o$  of 10 corresponds to a potential difference of 61 mV at 37 °C. Because their response to changes in  $\Delta\Psi$  is dependent upon their distribution across the cell membrane, lipophilic indicator cations are often described as **distributional probes**.

Once cells have been equilibrated with an indicator cation, **depolarization** of the cells will cause **release of indicator from cells into the medium**, while **hyperpolarization** will make **cells take up additional indicator from the medium**. The indicator distribution will not adequately represent the new value of  $\Delta\Psi$  until equilibrium has again been reached; this process requires periods ranging from a few seconds to several minutes. Thus, while distributional probes may be suitable for detection of slow changes in  $\Delta\Psi$ , they cannot be used to monitor the faster changes that occur during the propagation of action potentials in tissues such as nerve and muscle.

Most of the dyes now used as probes of  $\Delta\Psi$  were developed during a systematic search by Lawrence Cohen, of Yale University, and his coworkers<sup>457</sup> for materials that would exhibit rapid enough changes in optical characteristics to

respond to action potentials in nerve cells. Among the dyes evaluated were many that proved unsuitable because of their tendencies to redistribute across cell membranes in response to slow potential changes. As might be expected, most lipophilic cationic dyes fell into this category. One of these, **3,3'-dihexyloxycarbocyanine [DiOC<sub>6</sub>(3)]**, was studied by Hoffman and Laris<sup>458</sup>, who were able to make estimates of  $\Delta\Psi$  in red blood cell suspensions based on the partitioning of the dye into the cells.

The use of a lipophilic cationic dye as a distributional probe of  $\Delta\Psi$  involves only a slight departure from the distributional probe technique for  $\Delta\Psi$  estimation using radiolabeled lipophilic cations. The radioisotope method requires that a known volume of cells (or organelles, e.g., mitochondria) in suspension be equilibrated with the indicator; the intracellular and extracellular indicator concentrations are calculated from a determination of the amount of cell-bound indicator done by scintillation counting of the cells after washing to remove unbound indicator.

**Estimation of  $\Delta\Psi$  of cells in suspension using symmetric cyanine dyes<sup>458</sup>** is done in a spectrofluorometer. Addition of cells to micromolar solutions of dyes such as DiOC<sub>6</sub>(3) produces a suspension with lower fluorescence than that of the original solution, indicating that, **at micromolar external concentrations, the fluorescence of dye taken into cells is quenched**. When intracellular and extracellular ion concentrations are manipulated to hyperpolarize the cells, increasing cellular uptake of dye, the fluorescence of the suspension decreases further; when the cells are depolarized, releasing dye into the medium, the fluorescence of the suspension increases. The results obtained by Hoffman and Laris using this method to estimate  $\Delta\Psi$  in giant red cells from *Amphiuma* compared favorably with the results these authors obtained by microelectrode measurements.

This success led to a comparative study by Sims et al<sup>460</sup> in which 29 cyanine dyes were examined as indicators of  $\Delta\Psi$  in red cells and lipid membrane vesicles. This paper introduced the **abbreviated nomenclature for the cyanine dyes** that is now in general use, explained in Figure 7-12 (p. 313). The lipophilicity of cyanine dyes increases with the length of the alkyl side chains, i.e., as n in the formula "DiYC<sub>n</sub>(2m+1)" increases. The wavelengths of maximum absorption and emission are essentially independent of the alkyl side chain length, denoted in the formula by (n + 1), but increase with the length of the polymethine bridge between the rings, i.e., as m in the formula increases<sup>461</sup>. The quantum efficiency of the dyes is increased, and the absorption and emission maxima are shifted to longer wavelengths, in nonpolar solvents. Spectra of some symmetric cyanine dyes and of tandem conjugates of phycobiliproteins and cyanine dyes appear in Fig. 7-9 (p. 296); the wide range of spectral characteristics available results in large part from the early development of the dyes by Eastman Kodak and their exploitation as photographic sensitizers<sup>461</sup>.

The report of Sims et al<sup>460</sup> gave particular prominence to two dyes, **dipentylloxycarbocyanine [DiOC<sub>5</sub>(3)]** and

dipropylthiadicarbocyanine [ $\text{DiSC}_2(5)$ ], because they exhibited larger fluorescence changes than most of the other dyes in response to maximal hyperpolarization of the cells induced by the **potassium-selective ionophore valinomycin** (see reference 444 for an extensive discussion of ionophores), and because they were relatively stable and did not cause excessive lysis of cells.

Some people mistakenly assumed that  $\text{DiOC}_2(3)$  and  $\text{DiSC}_2(5)$  were the only cyanine dyes suitable for  $\Delta\Psi$  estimation; this caused some problems because these dyes, and many of the others described by the Yale group, were not available commercially. The many investigators worldwide who became interested in using dyes for  $\Delta\Psi$  measurements were supplied with them by Alan Waggoner<sup>462</sup>, now at Carnegie Mellon University, who was responsible for most of the chemistry in the Yale project. Most people did not realize that dyes such as  $\text{DiOC}_6(3)$  and  $\text{DiSC}_2(5)$ , which, respectively, can be substituted for  $\text{DiOC}_2(3)$  and  $\text{DiSC}_2(5)$ , were readily available from Eastman and other companies (Eastman's product line is now sold by Acros Organics, but the dyes remain widely available). Results typical of those obtained in cuvette measurements with cyanine dyes are shown in Figure 7-26.

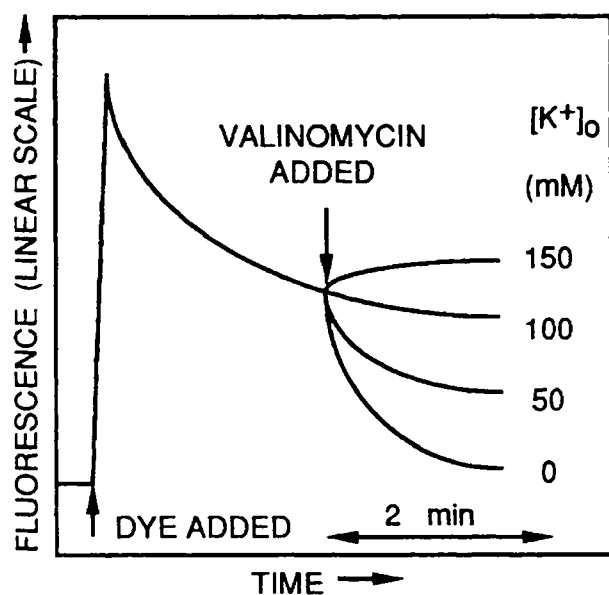

Figure 7-26. Valinomycin-induced changes in fluorescence intensity of red cell suspensions equilibrating with a cyanine dye at various external  $\text{K}^+$  concentrations.

Under normal circumstances, the intracellular concentration of  $\text{K}^+$ ,  $[\text{K}^+]_i$ , is considerably higher than the extracellular concentration  $[\text{K}^+]_o$ , while the intracellular concentration of  $\text{Na}^+$ ,  $[\text{Na}^+]_i$ , is considerably lower than the extracellular concentration  $[\text{Na}^+]_o$ . The ionophore **valinomycin** (VMC), which is lipophilic, forms a complex with  $\text{K}^+$  ions and can thus readily transport them across cell membranes. Addition of VMC thus effectively increases the cells' potassium per-

meability ( $P_K$  in the Goldman equation), to the point at which membrane potential is determined almost entirely by the transmembrane  $[\text{K}^+]$  gradient. If  $[\text{K}^+]_o$  is low, VMC addition hyperpolarizes cells; if  $[\text{K}^+]_o$  is high, VMC addition depolarizes cells, and, if  $[\text{K}^+]_i = [\text{K}^+]_o$ , VMC addition does not change  $\Delta\Psi$ .

Data such as those shown in Fig. 7-26 are obtained by normalizing curves so that the levels of fluorescence in each sample prior to VMC addition are identical. This normalization is necessary because even when the concentrations of cells and dye added to clean cuvettes are carefully controlled, equilibrium fluorescence readings obtained from cell suspensions vary due to such factors as dye adhesion to the cuvette walls. Despite this, people who worked with this technique for  $\Delta\Psi$  estimation developed the notion that cyanine dye fluorescence could somehow be calibrated to read out  $\Delta\Psi$  to the nearest millivolt. This was credible only as long as nobody looked at cyanine dye uptake at the single cell level. As far as I can determine (L. Cohen, personal communication; A. Waggoner, personal communication), cyanine dye-stained cells, other than nerve or muscle cells, weren't even looked at under a fluorescence microscope until I started playing with  $\Delta\Psi$  probes in the mid-1970's.

At that time, the literature stressed the point that  $\Delta\Psi$  estimation with cyanine dyes depended on **quenching of the fluorescence of intracellular dye**; in essence, the assumption was being made that all of the fluorescence measured in the cell suspension was coming from free dye in solution, or at least that the contribution of cell-associated dye to the total fluorescence signal remained constant. When I first looked at cells stained with micromolar concentrations of cyanine dyes, such as were used for  $\Delta\Psi$  estimation in suspensions, I expected to see dark cells against a fluorescent background, which would certainly not make it easy to adapt cyanine dye  $\Delta\Psi$  probes for flow cytometry. I was pleasantly surprised when I found brilliant fluorescence in the cells, and somewhat disappointed when I examined the broad fluorescence distributions (Figure 7-27, next page) obtained when they were run through a flow cytometer<sup>424</sup>.

### Single Cell Measurements with Distributional Probes

According to the Nernst equation (p. 386),  $[\text{C}]_i/[\text{C}]_o$ , i.e., the ratio of the intracellular and extracellular **concentrations** of a membrane-permeant cationic dye  $\text{C}^+$ , varies with  $\Delta\Psi$ . Since the extracellular concentration  $[\text{C}]_o$  is the same for all cells in a suspension, the intracellular concentration  $[\text{C}]_i$  should provide an indication of  $\Delta\Psi$ . If  $\Delta\Psi$  is the same in all the cells,  $[\text{C}]_i$  should be the same. However, the fluorescence distribution is not a distribution of dye concentration, i.e., of  $[\text{C}]_i$ , but of the **total fluorescence**, which we hope is proportional to the total amount of dye, per cell. To obtain a distribution of  $[\text{C}]_i$ , we need to divide the fluorescence value for each cell by the cell's volume, obtained by an electronic volume sensor or estimated from forward scatter or extinction; this is rarely done in practice.

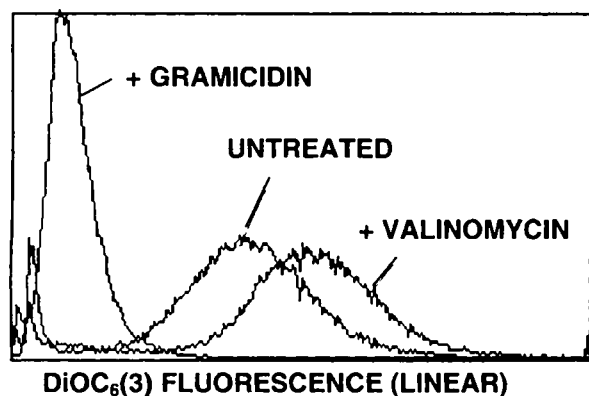

Figure 7-27. Distributions of the fluorescence of  $\text{DiOC}_6(3)$  in CCRF-CEM T-lymphoblasts equilibrated with 50 nM dye for 15 min. A: untreated cells, B: cells depolarized with gramicidin, C: cells hyperpolarized with valinomycin. The residual peaks at the left of the distributions represent signals from debris.

While volume measurements were not made of the cells that provided the data of Fig. 7-27, experience tells us that the coefficient of variation (CV) of the cell volume distribution of human peripheral blood lymphocytes is no more than 15%, while the CV of the cyanine dye fluorescence distribution observed in these cells is about 30%. Thus, variance of cell volume cannot explain all of the variance of the fluorescence distribution. Does this mean that there is a broad distribution of membrane potentials in lymphocytes? Not necessarily. The cells treated with the ionophore **gramicidin (GRM)**, which forms channels in the membrane that permit most mono- and divalent ions to pass through, should be completely depolarized, yet their fluorescence distribution also shows a greater variance than could be explained by cell-to-cell differences in volume.

Recalling that there are large potential gradients across mitochondrial membranes, you might be tempted to think that **mitochondrial uptake** of dye was responsible for the variance in fluorescence in the distributions of Fig. 7-27. This possibility was investigated; lymphocytes in which the mitochondrial potential was abolished using a combination of antimycin, dinitrophenol, and oligomycin did show less cyanine dye fluorescence (by 15-20%) than cells that were not exposed to these inhibitors, but the variance of the fluorescence distribution was not significantly reduced.

In cells treated with GRM,  $\Delta\Psi$  should be zero; and the concentrations of dye inside and outside the cells should therefore be the same. How is it, then, that we can manage to see the little buggers? Well, there are two reasons. The first is that the fluorescence of cyanine dyes is enhanced (approximately sixfold in the case of  $\text{DiOC}_6(3)$ , less for other dyes) when the dye is in a hydrophobic environment<sup>460</sup>. The second, which is quantitatively more important, is that the lipophilic character of the dye causes it to be concentrated in cells in the absence of a potential gradient because it binds to

intracellular material, predominantly lipids and membranous structures (a 1997 paper<sup>2801</sup> actually describes  $\text{DiOC}_6(3)$  as a "specific" stain for endoplasmic reticulum).

**C  
E  
L  
L  
#**  
In the study of Sims et al<sup>460</sup>, symmetric cyanine dyes with different alkyl side chain lengths were equilibrated with VMC-treated suspensions of red blood cells, which had been estimated to have a membrane potential of  $-40$  mV. The Nernst equation would predict that the ratio of intracellular and extracellular dye concentrations should be less than 10; the ratio observed for diethylthiadicarbocyanine [ $\text{DiSC}_2(5)$ ], the least lipophilic dye in the series, was over 100, and the ratios observed using other thiadicarbocyanine dyes increased with the length of the alkyl side chains, reaching a value above 10,000 for dihexylthiadicarbocyanine [ $\text{DiSC}_6(5)$ ]. Thus, while uptake of cyanine dyes does provide an indication of membrane potential, the association of these dyes with cells is distinctly "Non-Nernstian."

**Don't** try to measure membrane potential with cyanine dyes with heptyl or longer side chains, e.g.,  $\text{DiOC}_6(3)$ . In the series running from  $C_1$  through  $C_6$ , the longer chain dyes, which are more lipophilic, get in faster, which is an advantage. At  $C_7$  and above, the cyanines start to take on characteristics associated with the **cyanine tracking dyes** such as "DiI," "DiO," and the PKH series, discussed on pp. 45-6 and 371-4; they feel so warm and cozy in the lipid bilayer that they're not in any hurry to leave, even if the potential changes. The diheptyl ( $C_7$ ) cyanines, which are not widely used, can be thought of as the "missing link" between membrane potential probes and tracking dyes, which typically have alkyl side chains containing at least 14 carbons.

Non-Nernstian binding of probe is also encountered when  $\Delta\Psi$  is estimated with radiolabeled lipophilic cations such as  $^3\text{H-TPMP}$ . In order to get accurate values of cytoplasmic  $\Delta\Psi$  using lipophilic cationic indicators, it is necessary to inhibit the mitochondria and to correct the results to account for uptake in the absence of a potential gradient. Felber and Brand<sup>463-6</sup> produced a few papers that resolved several controversies in the previous literature regarding lymphocyte membrane potentials. Their work, unfortunately, did not extend to single cell measurements.

This still leaves us looking for an explanation of the variance of cyanine dye fluorescence distributions. Further comparison of flow cytometric data<sup>112</sup> with data obtained from cuvette measurements can be helpful in this regard. When flow cytometry is done on cells exposed to different concentrations of cyanine dyes, a point is reached at which increasing the dye concentration does not increase fluorescence in the cells. If the dye used is  $\text{DiOC}_6(3)$ , this happens when cells at a concentration of  $10^6/\text{ml}$  are incubated with 2  $\mu\text{M}$  dye. The variance of the fluorescence distribution remains large, suggesting that cyanine dye fluorescence in cells results from fluorescence enhancement of dye bound to hydrophobic regions, and that the variance of fluorescence is due primarily to cell-to-cell variations in the number of binding sites.

Further evidence in support of this hypothesis comes from the observation that when the hydrophobic binding sites are saturated, at a dye concentration of 2  $\mu\text{M}$ , the fluorescence distributions of cells are identical whether they are suspended in isotonic NaCl, in which they maintain normal  $\Delta\Psi$ , or in isotonic KCl, in which they are depolarized. In both cases, addition of VMC or GRM does not change cellular fluorescence. In other words, the cellular fluorescence no longer responds to changes in  $\Delta\Psi$ . However, if the fluorescence of cell suspensions equilibrated with 2  $\mu\text{M}$  DiOC<sub>2</sub>(3) in NaCl and KCl is measured in a spectrofluorometer, the potential difference will be detectable, and hyperpolarization caused by addition of VMC to the cells in NaCl will produce a demonstrable fluorescence change. This means that the cells contain dye that is essentially nonfluorescent due to quenching, as well as dye bound to hydrophobic sites in which fluorescence is enhanced. VMC addition causes uptake of additional dye, which is also quenched once it enters the cells. Quenching of the fluorescence of symmetric cyanine dyes typically involves the formation of **aggregates**. So-called **H-aggregates** are nonfluorescent, while fluorescent **J-aggregates** typically emit at wavelengths substantially longer than do single dye molecules.

The dye concentration at which saturation of binding sites occurs is determined primarily by the lipophilicity of the dye; the fluorescence of cells (at  $10^6/\text{ml}$ ) equilibrated with 2  $\mu\text{M}$  DiOC<sub>2</sub>(3), which is less lipophilic than DiOC<sub>6</sub>(3), is less than the fluorescence of cells equilibrated with the C<sub>6</sub> dye, and does change when  $\Delta\Psi$  is changed by ionophore addition or by manipulation of ion concentrations in the medium. In fact, if cells in 2  $\mu\text{M}$  DiOC<sub>2</sub>(3) in NaCl (normal  $\Delta\Psi$ , higher fluorescence) are mixed with an equal volume of cells in 2  $\mu\text{M}$  DiOC<sub>2</sub>(3) in KCl (depolarized, lower fluorescence), the cells and dye reequilibrate within a few minutes, as shown in Figure 7-28, yielding a fluorescence distribution that reflects the intermediate value of  $\Delta\Psi$  resulting from the ionic composition of the mixed suspending medium.

The distributions shown in Figure 7-28 are distributions of  $\Delta\Psi$  values estimated from the ratio of fluorescence and extinction signal amplitudes. This was done in an attempt to compensate for the effects of cell size variation in the cultured cell line used for the experiments, which results in broadening of the fluorescence distributions. The variance of the distributions of the fluorescence/extinction ratio remains fairly large, indicating that factors other than cell size contribute substantially to the variance in the number of sites to which dye binds with fluorescence enhancement.

From what has gone before, we can conclude that the cyanine dyes, under the best conditions, are not going to give us absolute values of  $\Delta\Psi$  to the nearest millivolt, whether we measure cell suspensions in cuvettes or individual cells in flow cytometers or microphotometers. However, while the fluorescence of cell-associated cyanine dye cannot provide an absolute measure of  $\Delta\Psi$ , it can provide a reasonably rapid indication of substantial changes in  $\Delta\Psi$  that

occur over periods of seconds to hours, and allow us to examine correlations between  $\Delta\Psi$  and other parameters.

The breadth of the distributions obtained by flow cytometry means that cyanine dye fluorescence has only limited capability for detecting heterogeneity of  $\Delta\Psi$  in populations; if 50% of the cells have  $\Delta\Psi$  values that are approximately half those of the other 50%, you'll know it, while if 5% of the cells exhibit a 15% increase in  $\Delta\Psi$ , you won't. Are there, then, any better dye probes of  $\Delta\Psi$  than the cyanines?

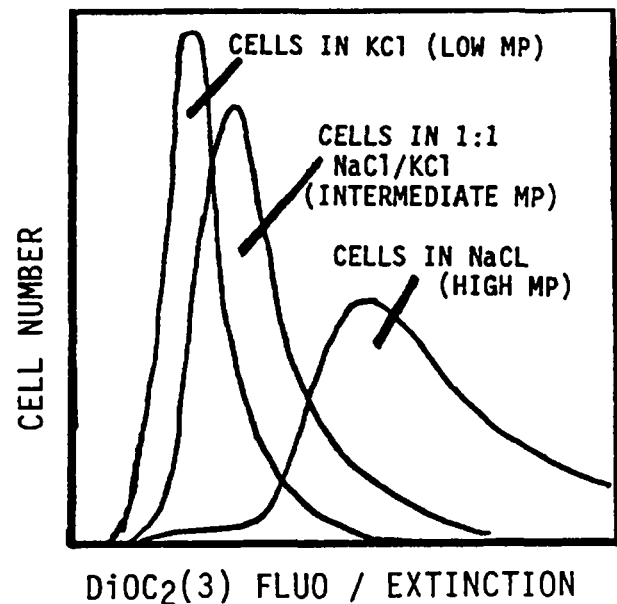

Figure 7-28. Distributions of MP ( $\Delta\Psi$ ) (estimated from the ratio of DiOC<sub>2</sub>(3) fluorescence to extinction) in cultured CEM lymphoblasts suspended in isotonic NaCl, isotonic KCl, and a mixture of the two.

It has already been mentioned that any cationic dye that crosses cell membranes readily can serve as a distributional probe of  $\Delta\Psi$ . Among the classes of such dyes that have been investigated by Cohen, Waggoner et al<sup>457,461,462</sup> and by others are **cyanines** (e.g., the classical mitochondrial stain **pina-cyanol** as well as the compounds discussed above), **acridines** (yes, acridine orange works as an  $\Delta\Psi$  probe if you use it at about 10 nM, but who needs it?), **oxazines** (e.g., Nile blue), **pyronins**, **rhodamines** (e.g., **rhodamine 123**), **safranins** (e.g., **Janus green**, well known as a mitochondrial stain, and **safranin O**) **styryl compounds** and **triarylmethane dyes** (e.g., **crystal violet**). I have done flow cytometry of cells stained with a reasonable number of cationic dyes from this list, and none of the dyes offers any obvious advantages from a metrologic point of view in flow cytometry, although some may be less toxic and/or more stable than the cyanines. Plášek and Sigler and their colleagues have refined calibration of cuvette measurements of  $\Delta\Psi$  using cyanine dyes, but have only obtained semiquantitative results using flow cytometry<sup>2802,4</sup>.

Leslie Loew and his colleagues<sup>16,76-8</sup> have described the use of the relatively hydrophilic methyl and ethyl esters of

tetramethylrhodamine for “Nernstian” membrane potential measurement by imaging microspectrofluorometry; by measuring dye concentrations in various spatial regions, these probes allow simultaneous determination of cytoplasmic and mitochondrial membrane potential, once corrections are made for contributions for dye from out-of-focus regions and for non-Nernstian binding.

### Oxonol Dyes as Membrane Potential Probes

**Oxonols**<sup>426,850-1</sup> (Figure 7-29), which are negatively charged, bind to the cytoplasmic membrane but do not accumulate in intact cells; probably because they do not enter cells at appreciable concentrations, they are much less toxic than cyanines and other cationic  $\Delta\Psi$  probes. For the same reason, oxonol fluorescence, unlike fluorescence from cationic probes, is not greatly influenced by potential-dependent uptake of dye into mitochondria. These desirable characteristics of oxonols are offset somewhat by their weaker fluorescence, as compared to cyanines, and, since they don't produce distributions with any less variance, than do cyanines, I don't use oxonols much. I also find that the bright staining of damaged cells by oxonols, which, being negatively charged and highly lipophilic, stick like crazy to everything inside cells once they get in, is something of a nuisance. This may be dealt with by adding a dye such as crystal violet or trypan blue to quench the offending fluorescence, but it gets to be too much of a production for my taste.

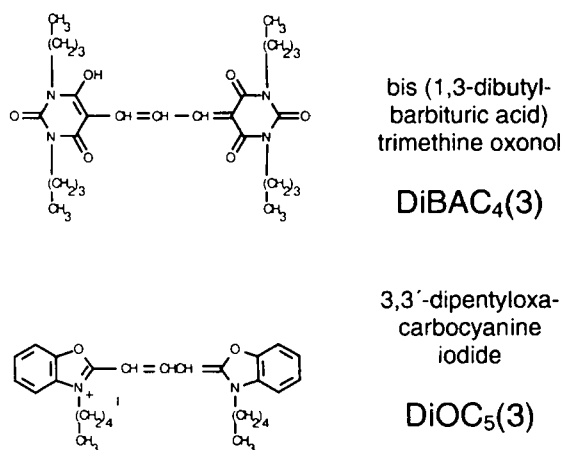

Figure 7-29. Structures of two of the more popular membrane potential probes, an oxonol and a cyanine. Structures were provided by Molecular Probes.

When I have compared oxonols and cyanines in rat and human leukocytes, T cells, and human lymphoblastoid cell lines, I have gotten pretty much the same results in terms of being able to detect depolarization and hyperpolarization. (oxonol-stained cells are brighter when depolarized and dimmer when hyperpolarized, a mirror image, if you will, of cyanine dye response). This is probably so because I make measurements over short time periods, which, combined

with the relative resistance of the cells I study to cyanine toxicity and the absence of significant mitochondrial interference with fluorescence, lets me get away with it. Ken Rosenthal and I grew cells in 2  $\mu\text{M}$  DiOC<sub>6</sub>(3) for a few days, in the dark, of course. People whose cells won't stand up to that have good reason to use oxonol dyes.

I have confidence in the estimates (calling them measurements would imply more accuracy and precision than dyes and flow cytometry can give us) of  $\Delta\Psi$  I get from cyanines, which do, after all correlate with microelectrode measurements<sup>458,852</sup>, but oxonols work. Krasznai et al<sup>2805</sup> described a method for determination of “absolute membrane potential” of cells using the popular oxonol DiBAC<sub>4</sub>(3), a dye that is frequently referred to as “bis-oxonol” but should not be, because it is one member of a large family of bis-oxonols. A calibration curve is constructed from a plot of fluorescence intensity measured from stained cells vs. extracellular dye concentration; it is assumed that dye distribution is Nernstian, which is probably a risky assumption given the lipophilicity of oxonol dyes. However, Krasznai et al reported good agreement between their flow cytometric measurements and patch clamp measurements.

When cells are added to solutions of oxonol dyes, the fluorescence of the resulting suspensions is increased. Oxonols, being negatively charged, should tend to remain outside cells with interior-negative membrane potentials; a purely Nernstian distribution for cells with  $\Delta\Psi = -61$  mV would make the internal oxonol concentration 1/10 of the external concentration. However, like most of the symmetric cyanines, the oxonols increase fluorescence in nonpolar solvents, with the result that any dye molecule bound to membranes or lipids becomes more fluorescent than it would be in aqueous solution. The lipophilicity of oxonols results in their being taken into cells against the electrochemical gradient across the cytoplasmic membrane, but the dyes are largely excluded from mitochondria by the electrochemical gradient across the mitochondrial membrane.

A careful choice of controls is required when oxonols are used. These dyes form complexes with valinomycin, complicating its use as a hyperpolarizing agent; monensin has been suggested as a replacement. The real danger, however, arises from using heat-killed or fixed cells as exemplars of cells with  $\Delta\Psi = 0$ , because both heat and fixation permeabilize cells and change the chemical structure of the membrane. The observed increased binding of oxonols is therefore likely to reflect influences of factors other than membrane potential, e.g., binding to intracellular proteins and changes in membrane asymmetry.

The binding of merocyanine 540, which can be envisioned as a chimerical combination of half a cyanine and half an oxonol, to cells is known to be influenced by changes in membrane asymmetry, hence the utility of that dye in detecting apoptotic cells. I have already (p. 374) noted my suspicion that at least some oxonol dyes may share the characteristics of their half-sibling, although I haven't done the experiments needed to prove the point. You're welcome to

try and beat me to it using merocyanine 540 and DiBAC<sub>3</sub> alternately with APC-annexin V in an apoptosis model system. In the meantime, stick with adjustments of the external potassium concentration or oxonol-friendly ionophores to get control cells with zero membrane potential.

### Possible Alternatives to Distributional Probes for Flow Cytometry of Membrane Potentials

Dyes that work as Nernstian probes of membrane potential are obviously just dandy for monitoring membrane potential changes in single cells in **static** or image cytometers; even with non-Nernstian dyes, making repeated observations of the same cell over time eliminates the otherwise vexing problem of cell-to-cell variability in fluorescence intensity. However, under the best of circumstances, distributional dyes can only be used to monitor relatively slow  $\Delta\Psi$  changes, occurring over periods of seconds to minutes. Better results would be expected using faster responding dyes, which sense membrane potential by different mechanisms.

The hardware technology for making static or imaging measurements is a lot simpler than it used to be, and it certainly seems easier than building a multistation flow system 100 meters long, which some of us have also thought of as a way to make repeated observations of the same cell several seconds apart. Because of the photodynamic toxicity of most membrane potential probes, however, you have to be careful, when making static measurements, about how you treat the cells between observations. For example, if you stain cells with a green-excited dye, you do all of the hunting for the cells under low-level red illumination using phase contrast and/or image intensification, thereby avoiding light and heat damage to the cells. When you want to measure the cells, you give them no more than a few milliseconds worth of green illumination at a time, using an arc or quartz lamp (with heat filters!!!) and a shutter, or else a xenon flash lamp. This minimizes photodynamic damage to the dye as well as to the cells. As long as you have several measurement values for the same cell, all you need to calculate is the percentage change in fluorescence in response to the stimulus applied, and you are largely unconcerned by the large cell-to-cell variations in fluorescence intensity that plague you when you do  $\Delta\Psi$  estimation by flow cytometry.

As I mentioned previously, the distributional dye probes of  $\Delta\Psi$  emerged as a spinoff of a project designed to find dyes that could respond within milliseconds to changes in nerve membrane potentials. The first dyes from which Cohen et al got fast responses typically showed fluorescence or absorption changes of about 0.1% in response to a 100 mV change in  $\Delta\Psi$ . One of these, merocyanine 540<sup>467</sup> (see above), was found to stain immature and leukemic but not normal leukocytes; the staining appeared to be independent of  $\Delta\Psi$ , but if the fluorescence had changed by 0.1% on VMC addition, nobody would have noticed. No need to worry about membrane potential affecting merocyanine fluorescence in the experiment suggested above.

Better **fast-response  $\Delta\Psi$  probes** have since emerged from continued development efforts; one of the best dyes available a few editions back was a styryl compound that exhibited a 21% fluorescence change in response to a 100 mV potential change<sup>468</sup>. Believe it or not, this still wasn't good enough for flow cytometry. If we are looking for a 10 mV depolarization in mitogen-stimulated lymphocytes<sup>465</sup>, we can expect to get a 2% fluorescence change in the best dye probe under the best circumstances, and we'd need an instrument CV of less than 1% to be able to detect it. That's one flow cytometer I can't tell you how to build. If you could build it, it wouldn't help, because cells stained with the fast **oxonol**, **merocyanine**, and **styryl** dye probes produce fluorescence distributions with the same large variances seen in cyanine dye fluorescence distributions.

### Ratiometric Probes for Membrane Potential

Is there a way to make this a real measurement, i.e., to improve the accuracy or, more to the point, decrease the variance, of distributions observed in flow cytometric  $\Delta\Psi$  estimation? Several possibilities suggest themselves. I have mentioned that the ratio of  $[C']/[C]_o$  in cells varies with the lipophilicity of the dye  $C'$  as well as with  $\Delta\Psi$ . If two cyanine dyes of differing lipophilicities, e.g., a  $C_2$  dye and a  $C_6$  dye, are added to cells, the ratio of intracellular concentrations of the two dyes should vary with membrane potential. Since the dyes presumably bind to the same hydrophobic sites in cells, cells with more sites should take up more of both dyes. Thus, the cell-to-cell variation in numbers of binding sites should not affect the ratio of concentrations of the two dyes in cells. This ratio could therefore be used as an index of  $\Delta\Psi$ . In order to get this methodology to behave, however, you have to use a multistation system and two dyes with widely separated spectra; otherwise, energy transfer comes in and confuses things.

The **fast potential probes** respond to membrane potential changes by **changing their position and/or orientation in the membrane**; it is claimed that most do not penetrate to the cell interior. Since all of the transmembrane potential difference is developed across the thickness of the membrane, the electric field strength in the membrane itself can be quite high. Loew<sup>469</sup> has designed electrochromic  $\Delta\Psi$  probes that undergo spectral changes in responses to changes in the applied electric field. The current champ is **di-4-ANEPPS** [1-(3-sulfonato-propyl)-4-[beta-[2-(di-*n*-butyl-amino)-6-naphthyl] vinyl] pyridinium betaine], which responds via a rapid (less than millisecond) spectral shift to membrane potential changes<sup>1679</sup>. The problem with this dye is that the electric field affects the excitation, rather than the emission, spectrum of the dye; you need a blue and a green excitation beam (441 nm from a He-Cd laser and 515 nm from an argon laser would do), and the membrane potential is calculated from the ratio of fluorescence intensities at 610 nm excited by the two sources. It may not be worth putting together a fancy flow cytometer to try the measurements; Chaloupka et al<sup>2806</sup> attempted cuvette measurements of

$\Delta\Psi$  in *Saccharomyces cerevisiae* using di-4-ANEPPS, and found that the probe was not localized to the cell membrane and that the magnitudes of responses increased with time, and I suspect that taking a ratio won't cure all of those ills.

Loew's group<sup>1680</sup> also reported that the nonlinear optical phenomenon of **second harmonic generation**, which is responsible for the frequency doubling properties of crystals used in the laser industry, is sensitive to membrane potential; they have found a dye that gives a big signal, but it would definitely require more in the way of excitation power than most of us have in our flow cytometers.

Looking toward simpler solutions, we might reason that if the variance in distributions of cationic dye fluorescence in cells arises because of cell-to-cell variations in the number of dye binding sites, we ought to be able to do dandy  $\Delta\Psi$  measurements, at least on things like peripheral blood lymphocytes, if we can find a lipophilic cationic DNA fluorochrome. If we then add dye at lower concentrations than are needed to get stoichiometric staining of DNA, so as to be sure that some dye binding sites remain available, the fluorescence histogram we get should be a histogram of  $\Delta\Psi$ , shouldn't it? Yes, if the dye stains DNA and doesn't stain all kinds of other stuff in the cytoplasm. Most of the symmetric monomethine cyanine dyes, e.g., DiOC<sub>2</sub>(1), DiSC<sub>2</sub>(1), DiQC<sub>2</sub>(1), and DiLC<sub>2</sub>(1), stain cell nuclei, and show fluorescence enhancement when bound to DNA, but they stain cytoplasmic constituents as well. Some blue- and green-excited cationic DNA fluorochromes described by Latt et al<sup>470</sup> seem to present the same problems with nonspecific staining. The asymmetric cyanines, such as thiazole orange and thiazole blue, should be good candidates, except that they're not DNA-specific. I would bet that a suitable dye exists, but not on when someone will find it.

Farinas<sup>2807</sup> et al have managed to come up with a flow cytometric ratiometric technique for membrane potential measurement that uses an asymmetric cyanine dye; they measure fluorescence of DiBAC<sub>4</sub>(3) and SYTO-62 in a slow-flow microfluidic system. The ratio of fluorescence of the two dyes changes by approximately 2% for each 1 mV change in membrane potential. The measurement is not made at equilibrium; instead, mixing fluidics insure that the time interval between dye addition and observation is constant (see p. 365). I don't see why the measurement wouldn't work in a more conventional instrument with appropriate sample handling hardware.

Gonzalez and Tsien<sup>2356,2808-9</sup> have described (and, via **Aurora Biosciences**, now part of **PanVera**, patented) a high-sensitivity, fast-response ratiometric method for measuring cytoplasmic  $\Delta\Psi$  that also uses oxonol dye fluorescence, but in a far more specific way. Oxonols bind to both the inner and the outer face of the cytoplasmic membrane; as cells depolarize, dye shifts from the outer face to the inner face, while, as cells hyperpolarize, dye shifts from the inner face to the outer face. Gonzales and Tsien made energy transfer (FRET) measurements using fluorescently labeled lectins<sup>2808</sup> and, later, fluorescently labeled fatty acids<sup>2809</sup> as

donors, and oxonols as acceptors, using the ratio of acceptor fluorescence to donor fluorescence as an indicator of  $\Delta\Psi$ . They achieved the best sensitivity with coumarin-labeled phosphatidylethanolamine as the donor and bis(1,3-dihexyl-2-thiobarbiturate)trimethine oxonol as the acceptor, with the fluorescence ratio changing 50% for a 100 mV change in  $\Delta\Psi$ . This is the highest sensitivity ever reported for a fast response (< 2 ms) method. An even faster response (< 0.4 ms, shorter than the duration of nerve action potentials) was achieved using a pentamethine oxonol acceptor.

I'll discuss another, lower-tech, ratiometric membrane potential measurement technique, useful for bacteria, later on.

### Using Cyanine Dyes for Flow Cytometric $\Delta\Psi$ Estimation, In Case You're Still Interested

Now, if things are as bad as I have said, why does anybody bother using cyanines – or other dyes – for flow cytometric estimation of cytoplasmic  $\Delta\Psi$ ? I can tell you why I use them; I have a good idea of the limitations of the reagents and the technique and I only use them when I don't need a more precise estimation of  $\Delta\Psi$  than they can give me. You now know most of what I know about the limitations; if you're still interested in using the technique, here's how.

The dye I personally use most often is DiIC<sub>6</sub>(5), otherwise called **hexamethylindodicarbocyanine** and sometimes known as HIDC, which is available from Molecular Probes and (as a laser dye) from several other companies. I use DiIC<sub>6</sub>(5) because its fluorescence can be excited with a red He-Ne or diode laser and measured through 665 nm long pass glass filters (or 660-670 nm bandpass interference filters) using an R928 or other red-sensitive PMT. When I work with 488 nm excitation, I usually use **dihexyloxacarbo-cyanine** [DiOC<sub>6</sub>(3)] or **hexamethylindocarbo-cyanine** [DiIC<sub>6</sub>(3)], the latter also known as acronol phloxine. DiOC<sub>6</sub>(3) is green fluorescent and can be used with the same detector/filter combination used for fluorescein; DiIC<sub>6</sub>(3) is orange fluorescent. I tend to use the C<sub>6</sub> dye at a final concentration of 50 nM and the others at 100 nM to 1  $\mu$ M.

I make up 1 mM stock solutions of dye in DMSO and keep them in the dark at room temperature. I make working solutions by diluting the stock solution with ethanol so that I can reach the desired final dye concentration by adding 5  $\mu$ l of working solution to each 1 ml of cell suspension. Since the dye really hates to hang around in aqueous solution, the cells tend to suck up most of it. As a result, you need to keep the cell concentration with which you work fairly constant; I generally shoot for 10<sup>6</sup>/ml because that's a good concentration to use for flow cytometry.

If you are working with cells in protein-free media, dye equilibration is usually complete after 15 minutes at room temperature. If there's protein in the medium, I give the cells about 30 minutes at 37 °C. It's important to keep the incubation temperature and the interval between dye addition and introduction of the sample into the flow cytometer

constant, and it's not a bad idea to run all samples in an experiment at the same flow rate, because this is an equilibrium staining procedure.

If the experiment you are doing extends over a period of a few hours, it's important to run controls during the course of the experiment as well as at the beginning and end. Controls should include an untreated cell sample, a sample of cells hyperpolarized by addition of 5  $\mu\text{M}$  valinomycin (VMC), and another sample depolarized by addition of 10  $\mu\text{M}$  gramicidin (GRM) (this assumes you are working with cells in a high- $\text{Na}^+$ , low- $\text{K}^+$  medium). If you have any doubt about the health of your cells, make up a triple-dip sample of control cells, measure them after they have equilibrated with dye, and then add VMC to what's left of the sample. If the fluorescence of the cells doesn't increase, either the cells are dead or you've used too much dye. If it does increase, add GRM to the remaining cells; they should depolarize. If they don't, something's wrong. VMC, by the way, will not hyperpolarize cells after GRM addition has depolarized them, so make sure you do things in the right order.

I should also remind you that cyanines and other positively charged dye probes of membrane potential are subject to eviction from cells by the **glycoprotein drug efflux pump** (pp. 376-7). This is not as much of a problem when you're doing measurements of cytoplasmic membrane potential, and leaving cells in equilibrium with the dye, as it is when you're looking at mitochondria, and have to wash the cells. Washed cells with an active pump lose dye, period; equilibrated cells with an active pump come to equilibrium with lower concentrations of dye than they would if the pump weren't there, but the intracellular dye concentration still responds to membrane potential changes. If you're paranoid about the pump, use 100 nM DiBAC<sub>3</sub>(3); this oxonol dye is unaffected by it.

By following the procedures I have just described, you should be able to establish that the cells with which you are working have a nonzero potential difference across their cell membranes, and that the indicator dye you are using will respond to potential changes in either direction from the control value. You can then examine the effects of the biological, chemical, or physical agents you are studying on the cells'  $\Delta\Psi$ .

It is advisable to keep the cells happy if you want them to continue responding over the course of a few hours. If the buffer capacity of the medium won't stand up to the metabolic output of the cells, you may get funny results because pH does have some ill-defined effects on  $\Delta\Psi$  probes. If you are working with blood cells, avoid using  $\text{NH}_4\text{Cl}$  or a hypotonic medium to lyse red cells; the former depolarizes cells<sup>471</sup>, and the latter may change cation contents (and thus presumably  $\Delta\Psi$ ) and cell volumes of different cell types in different ways<sup>472</sup>.

If you add practically any protein to a cell suspension that has been equilibrated with a cyanine or other lipophilic cationic indicator in a protein-free medium, the indicator concentration in cells will decrease because the indicator will

bind to the protein in solution. When you do the measurement, it looks as if the cells have depolarized, but they probably haven't. If you're trying to find the effects of adding various proteins to cells, work in a medium with added protein, e.g., 1-10% albumin.

Similar artifactual "depolarization" may appear when you add appreciable concentrations of nonpolar solvents to a dyed cell suspension, which is why it's a good idea to keep the total amount of added DMSO, EtOH, etc. relatively constant from sample to sample and not add amounts of these solvents in excess of 1% of sample volume. If you are adding material dissolved in DMSO, make sure the sample is well mixed, because DMSO, left to its own devices, will sit at the bottom of an aqueous solution, and the hydrophobic molecules in it may be content to stay there unless prodded.

If you want to eliminate mitochondrial influences on the uptake of cyanines or other lipophilic cationic dyes, you can add an **uncoupler**. Felber and Brand<sup>463</sup> used 5-10  $\mu\text{M}$  **carbonyl cyanide p-trifluoromethoxy-phenylhydrazone (FCCP)** in their TPMP' procedure; I have tried this a few times and it seems to work. Waggoner<sup>462</sup> cautions that the related uncoupler **carbonyl cyanide chlorophenylhydrazone (CCCP)** may interfere with cuvette measurements using DiSC<sub>3</sub>(5); I have used CCCP at 5-10  $\mu\text{M}$  for flow cytometry without problems.

For the record, I have tried to measure  $\Delta\Psi$  in cell suspensions in cuvettes using cyanine dyes on several occasions, and have only succeeded once; the flow cytometric procedure done on cells from the same samples at the same time has worked. Oxonol dyes, which are nontoxic and which respond to  $\Delta\Psi$  changes more rapidly than do cyanines, have been advocated as superior  $\Delta\Psi$  probes for cuvette measurements by Tsien, Pozzan and Rink<sup>426</sup>; I'll try them if I ever have occasion to attempt more cuvette measurements.

Also for the record, there have been occasions when we shut off a flow cytometer after running cyanine dye-stained lymphocytes from one donor on one day, turned the system on again the next day, and found that the peak of the distribution of fluorescence from another donor's cells was within a few channels of the peak of the distribution obtained the day before. From my point of view, the flow cytometric technique is more reproducible than is the bulk measurement method.

There have been a lot of bad things said about cyanine dyes in the literature, many of which are true. At micromolar concentrations, cyanines have been observed to be toxic to bacteria<sup>473</sup> and mammalian cells<sup>474,7,1683</sup>. The dyes themselves may perturb  $\Delta\Psi$  directly by altering membrane conductivity; their inhibition of energy metabolism may also result in  $\Delta\Psi$  changes. When used to monitor neutrophil  $\Delta\Psi$  responses to chemotactic peptides, DiOC<sub>6</sub>(3) and TPMP' have been reported to give contradictory results<sup>478</sup>, while DiSC<sub>3</sub>(5) was found to be destroyed by oxidation following neutrophil activation<sup>479</sup>.

The affinity of cyanine dyes for cell constituents is so high, and their solubility in water so low, that you can end

up with inconclusive results when you use very low concentrations of dye and relatively high concentrations of cells, simply because the dye molecules grab on to the first cells they see<sup>854</sup>. Olive and Durand have taken advantage of this property and used DiOC<sub>3</sub>(3), which I told you not to use as an  $\Delta\Psi$  probe, as an indicator of perfusion or penetration of materials into tumor cell spheroids<sup>854</sup>.

The toxicity of the cyanine dyes is a liability shared in common with other families of cationic dyes and with lipophilic cations such as TPMP<sup>+</sup>; when the cyanines are used in flow cytometry, at concentrations of 5-100 nM, toxicity is less than when radiolabeled cations or cationic dyes are used at micromolar concentrations for bulk measurements. Different cell types appear to have different degrees of susceptibility to cyanine dye toxicity; Crissman et al<sup>855</sup> found that simultaneous staining with DiOC<sub>3</sub>(3) improved both Hoechst 33342 staining of live CHO cells and cell survival following sorting, possibly because of effects on the efflux pump, while the supposedly less toxic rhodamine 123 affected neither staining nor survival. While this may not lead to the routine appearance of cyanine dyes in multivitamin pills, it does remind us that one cell's poison may be another cell's medium.

### Cytoplasmic Membrane Potential: Summing Up

It is hardly feasible to make microelectrode measurements of  $\Delta\Psi$  in large numbers of cells, and impalement with microelectrodes is probably more traumatic to lymphocytes than to squid axons. Despite this, cationic dyes such as the cyanines, radiolabeled cations, the anionic oxonol dyes, and microelectrodes have produced comparable results in most systems to which two or more measurement methods have been applied.

Tasaki and Byrne<sup>1684</sup> studied the time course of the intrinsic birefringence change of axons that coincides with action potentials, and attribute it to swelling of the nerve brought about by movement of water into the superficial layer of the axon. A close relationship was also demonstrated between nerve swelling and changes in light scattering and in dye absorbance. The intrinsic optical changes, by the way, are on the order of a few parts per ten thousand; you won't be noticing them on your scatter channel, and we'll probably have to stick with using dyes for flow cytometric measurements.

In looking at some studies<sup>1685-93</sup> on flow cytometry that emerged prior to the previous edition, I noticed that at least as many people seemed to use cyanines<sup>1687-9</sup> as oxonols<sup>1690-1,1691</sup>. Seamer and Mandler<sup>1691</sup> applied my trick of dividing by a size measure (Figure 7-28, p. 389) to lower the CVs from oxonol measurements. Damjanovich and Pieri<sup>1692</sup> correlated fluorescence flow cytometry with patch clamp measurements in lymphocytes. Radosevic et al<sup>1693</sup> used DiBAC4(3) to study membrane potential in conjugates of cytotoxic NK cells, which were labeled with a tracking dye, and K562 target cells. Conjugates could be identified on the basis of tracking dye fluorescence and light scattering signals; using a slit-scan

technique, the membrane potential of each cell in a conjugate was measured separately, showing that depolarization of the K562 cell occurs as a consequence of the cytotoxic activity of the NK cell. In at least some of the studies in this group<sup>1687,8</sup>, in which cyanine dyes were used, I suspect that the efflux pump had some effect on results. Watch out.

### Mitochondrial Membrane Potential ( $\Delta\Psi_m$ )

#### Mitochondrial Staining with Rhodamine 123 Is Membrane Potential-Dependent

Since 1980, numerous investigators have used the lipophilic cationic dye **rhodamine 123** for investigations of mitochondrial structure and function; it is appropriate at this point to discuss the general issue of **estimation of mitochondrial membrane potential (which I will abbreviate as  $\Delta\Psi_m$ ), as opposed to cytoplasmic membrane potential ( $\Delta\Psi$ )**, and to clear up some misconceptions that seem to have arisen concerning this particular dye.

As was mentioned on p. 385, there is normally a relatively large (100 mV or more, interior negative) gradient of electrical potential across mitochondrial membranes in cells. The electrical potential and pH gradients between the cytosol and the mitochondrial matrix are inextricably linked to the processes of **energy metabolism**<sup>487,8</sup>. When cells with normal mitochondrial function are allowed to equilibrate with lipophilic cations, potential differences alone generate gradients of cation concentration across mitochondrial and cytoplasmic membranes, with the concentration being highest in the mitochondria.

According to the **Nernst equation** (p. 386), the ratio of mitochondrial to cytosolic (free) cation concentrations should be 100:1 if the potential difference across the mitochondrial membrane is 120 mV, and 1000:1 if it is 180 mV. The presence of any high-affinity binding sites for the cation within mitochondria will result in the ratio of concentrations of (free + bound) cation in mitochondria and cytosol being higher than that predicted by the Nernst equation, unless there are much greater numbers of high-affinity binding sites within the cytosol.

If cell samples are allowed to come to equilibrium with equal concentrations of a series of cationic dyes of similar structure with increasing lipophilicity (e.g., cyanines), higher mitochondrial/cytosolic dye concentration ratios should be found for the dyes with higher lipophilicity (in the case of the cyanines, those dyes with longer alkyl side chains), due to increased binding to hydrophobic membrane structures, which are at least as abundant in mitochondria as in the cytoplasm. The ratio of intracellular and extracellular dye concentrations,  $[C']/[C]_o$ , should also increase with lipophilicity.

Under the equilibrium conditions just described, both cytoplasmic ( $\Delta\Psi$ ) and mitochondrial ( $\Delta\Psi_m$ ) membrane potential affect the total amount of dye taken up and bound by cells. The relative contributions of cytoplasm and mitochondria to the cytoplasmic " $\Delta\Psi$ ," as estimated by fluores-

cence of cells following equilibration with dyes such as cyanines, are, however, difficult to estimate *a priori*, because the total amount of dye in each compartment is the product of concentration and volume. In addition, one cannot expect to measure the same amounts of fluorescence emission from equal amounts of intra- and extramitochondrial dye, because quenching increases with dye concentration.

If cells are washed following a first equilibration with dye, the rate at which a new equilibrium between intramitochondrial, cytosolic, and extracellular dye concentrations is reached should be dependent upon mitochondrial affinity for the dye, because, after washing, the mitochondria serve as the primary source for redistribution of dye into the cytosol and thence into the extracellular medium. More and/or stronger mitochondrial binding of dye should be reflected in longer reequilibration times and, until equilibrium is reached, in higher ratios of intra- to extramitochondrial dye concentrations. Observation of such cells under a fluorescence microscope should show dye fluorescence to be confined to the mitochondria.

All that can be concluded, however, from the observation of fluorescence in the mitochondria of washed cells, or from microphotometric or flow cytometric measurement of cellular fluorescence under such conditions, is that the mitochondria were energized prior to dye addition and probably remained energized at the time of measurement; variations in  $\Delta\Psi_m$  cannot be inferred from variations in cell fluorescence. This is so because the number and/or volume of mitochondria may vary from cell to cell and because mitochondrial fluorescence itself is likely not to be proportional to  $\Delta\Psi_m$  due to concentration quenching. Recall (p. 388) that the ratio of concentrations of cyanine dyes inside and outside cells is typically at least several hundred, much higher than would be predicted by the Nernst equation; even if the ratio between cytosolic and mitochondrial concentrations is purely Nernstian, one can expect the concentration of dye in the mitochondria to be on the order of  $10^4$  times the external dye concentration. If the external dye concentration were only 10 nM, the mitochondrial concentration would be 100  $\mu$ M, and one would expect dye fluorescence to be substantially quenched.

If the mitochondria are **deenergized**, i.e., if  $\Delta\Psi_m$  is reduced to or near zero, before dye is initially added to the cells, e.g., by addition of a **metabolic inhibitor**, e.g., an **uncoupler** of oxidative phosphorylation, such as **CCCP**, no mitochondrial concentration of dye occurs in the first place, other than that which might result from dye binding to membranous structures in the absence of a potential gradient. Under these circumstances, the dye concentration in cells left in equilibrium with dye responds to differences in (cytoplasmic)  $\Delta\Psi$ , and flow cytometric fluorescence and cell size measurements can provide valid, semiquantitative estimates of this parameter provided dye concentrations are kept low, as discussed on p. 392, to minimize saturation and concentration quenching effects. Pretreatment with an inhibitor of mitochondrial energy metabolism similarly allows valid

estimates of cytoplasmic  $\Delta\Psi$  to be derived from uptake of TPMP' and similar substances.

If no inhibitor is added to cells, and they are examined while in equilibrium with dye, differences in fluorescence will be observed between cells with intact membranes and normal mitochondrial function, on the one hand, and damaged cells, on the other. Cells with deenergized mitochondria will, as just discussed, take up less dye than cells with intact energy metabolism; cells with cytoplasmic membrane damage sufficient to diminish or abolish the cytoplasmic  $\Delta\Psi$  gradient will also take up less dye. Thus, equilibrium dye fluorescence measurements in cells can provide an indication of **cell viability** that is based upon **metabolic integrity** as well as membrane integrity.

**Washing cells** before measurement can be expected to produce some improvement in live-dead cell discrimination. If mitochondria are deenergized before equilibration with dye, very little fluorescence will be seen in washed cells even if the cytoplasmic membrane is intact. If mitochondria become deenergized after equilibration with dye, but before washing, some concentration of dye in mitochondria may be observed if high-affinity binding results in dye being lost relatively slowly from the mitochondria. If the mitochondria become deenergized after washing, dye should be lost from the mitochondria into the cytosol at a rate dependent upon the affinity of mitochondria for the dye.

Viewed against this background, the observed behavior of **rhodamine 123 (R123)** in mitochondria and cells is no different from what would be expected, and not markedly different from what would be expected and has been observed using other dyes. During the fall of 1979, when my initial publication on flow cytometric  $\Delta\Psi$  estimation<sup>424</sup> and their first paper on R123 staining of mitochondria<sup>489</sup> were in press, Lan Bo Chen and Lincoln Johnson asked me if they could look at some R123-stained cells in one of my flow cytometers. We got to talking about membrane potentials; when I found out that R123 was a cationic dye I suggested that the mitochondrial staining they were seeing was potential-dependent, and we exchanged samples of dyes.

The R123 staining technique Johnson et al described<sup>489</sup> involved a 30 min equilibration of cells with 10  $\mu$ g/ml (about 25  $\mu$ M) R123, following which cells were washed and examined. Using that concentration of R123, I couldn't measure unwashed cells in the flow cytometer because of the intense background fluorescence. Backing off to 1  $\mu$ M, I found (unpublished) that I could get R123 fluorescence to respond to the usual  $\Delta\Psi$  manipulations involving VMC, GRM, and changes of ( $K^+$ ) concentration in the same fashion as did the cyanines. Johnson and Chen<sup>490</sup> established that R123 staining was dependent upon the presence of the mitochondrial  $\Delta\Psi$  gradient. They also observed that cells equilibrated with safranin and the cyanine dyes showed potential-dependent mitochondrial staining. In fact, cyanine dye-stained cells could be examined without washing, probably because cyanines are considerably more lipophilic than is R123, which should make the ratio of intra- and

extramitochondrial dye concentrations at least somewhat higher for the cyanines.

A few weeks after these experiments were done, Paul Horan and coworkers exhibited pictures of cyanine dye-stained fibroblasts at the 1979 Asilomar conference on Analytical Cytology; these showed dye concentrated in mitochondria. Horan et al found, as did Johnson et al using R123, that stimulation of confluent fibroblasts by wounding caused an increase within minutes in mitochondrial fluorescence in cells adjacent to the damaged areas<sup>491</sup>. Until both groups published in 1981, however, most people who were aware of the capacity of R123 to stain mitochondria were unaware of the central role of mitochondrial  $\Delta\Psi$  in R123 staining.

James and Bohman<sup>492</sup>, for example, used R123 and flow cytometry to study proliferation of mitochondria during the cell cycle of HL-60 cells, and Darzynkiewicz et al<sup>493</sup> reported increased R123 staining of stimulated lymphocytes beginning approximately 24 hr following exposure to lectins, attributing most of the increase in fluorescence to an increase in the number of mitochondria per cell, in work submitted for publication before reports of the potential dependence of R123 staining appeared in print.

The R123 fluorescence response in lymphocyte activation was not surprising to me because I and others<sup>425,456,484</sup> (also M. Brand, personal communication), using TPMP', microelectrodes, DiOC<sub>6</sub>(3), and TPMP', respectively had found apparent hyperpolarization of lectin-stimulated T lymphocytes beginning at 5-12 hours, and usually preceding increases in RNA content as measured with pyronin Y. I also noted (unpublished) that R123 staining increased in stimulated T cells; an example of typical results obtained from lymphocytes stained with Hoechst 33342 in combination with various other probes appears as Figure 7-30.

In retrospect, some of the differences in R123 fluorescence between resting and stimulated lymphocytes may reflect behavior of the glycoprotein pump, which appears to be more active in resting than in stimulated cells, leading to observable differences in the fluorescence of Hoechst 33342 in when cells are equilibrated at lower concentrations of the dye than are typically used for stoichiometric DNA staining<sup>248,50,253,257</sup> (see pp. 309 and 376).

I had suggested<sup>494</sup> that flow cytometric  $\Delta\Psi$  measurements might provide a more sensitive indicator of cell viability than was given by dye exclusion tests. This was of interest to several of my colleagues because it might provide a fast means for determining the effects of chemotherapeutic agents on cancer cells. Sam Bernal, Lan Bo Chen and I<sup>495</sup> looked at the effects of various drugs on R123 fluorescence in L1210 mouse leukemia cells, and concluded that loss of R123 fluorescence was a better and earlier predictor of loss of clonogenicity than were dye exclusion tests. However, later work (E. Adams, B. K. Bhuyan et al, presentations at the 1984 Cell Kinetics Society meeting and personal communications) showed that, while loss of R123 fluorescence generally indicates loss of clonogenicity, cells exposed to

lethal doses of some drugs may not lose R123 fluorescence for some time. Bhuyan et al demonstrated by biochemical analyses that R123 fluorescence parallels mitochondrial ATP content, and that the changes in this parameter following lethal doses of different agents occur with different time courses.

When R123 first came into use, great stress was placed upon its relatively low toxicity as compared to dyes such as the cyanines. Darzynkiewicz et al<sup>340</sup>, however, found that R123 inhibited the growth and cell cycle progression of cultured cells, while uncharged rhodamine dyes, which were not taken into mitochondria, were not inhibitory. Chen's group, which had reported different patterns of retention of the dye in normal and transformed cells<sup>496</sup>, thereafter discovered a selective toxic effect of R123 on carcinoma cells *in vitro*<sup>497</sup> and *in vivo*<sup>498</sup>. They have since established that the dye interferes with mitochondrial energy metabolism<sup>499</sup>.

CONTROL 48 HR PHA

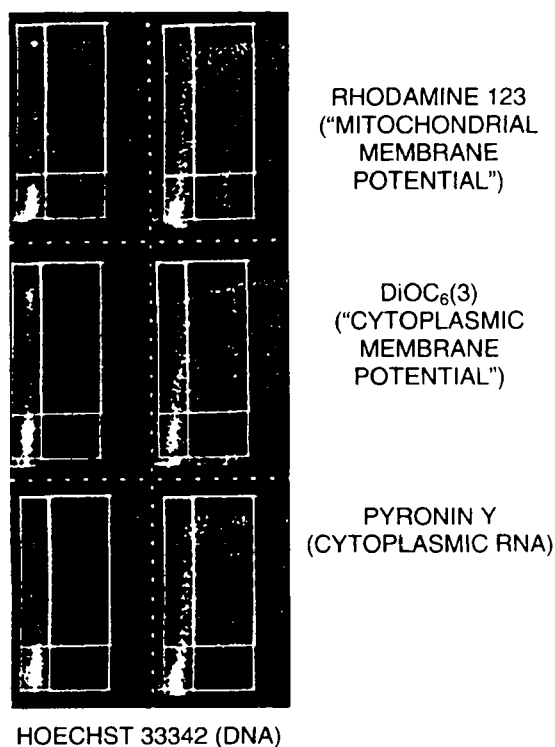

Figure 7-30. Two parameter flow cytometric analyses of lectin-stimulated human peripheral blood lymphocytes 48 hr after PHA addition.

The toxicity of the more lipophilic cyanine dyes, and of lipophilic cations such as TPMP', relative to R123 must be examined in the light of the fact that differences in lipophilicity exert profound effects on partitioning of the dye between mitochondria, cytosol, and medium. In cells equilibrated with equimolar concentrations of R123 and a lipophilic cyanine such as DiOC<sub>6</sub>(3), the intramitochondrial concentration of the cyanine dye may be hundreds of times higher than that of R123. Conversely, there exist other fluo-

rescent probes of mitochondrial energization which, like R123, are relatively water-soluble, and which are also said to be nontoxic; e.g., the styryl dyes **DASPMI (dimethylaminostyrylpyridinium iodide)** and **DASPEI** described in 1976 by Bereiter-Hahn<sup>500</sup>. The studies of R123 as an anticancer drug recalled the therapeutic use of DiSC<sub>2</sub>(5) as an antihelminthic agent under the name Dithiazanine<sup>501</sup>. I have often wondered whether some of the unexplained sudden deaths associated with this dye/drug were related to the observation by uninformed patients of brilliant blue stools following its oral administration. In a more serious vein, it should be pointed out that Zigman and Gilman<sup>475</sup> have related the toxicity of cyanine dyes to redox potential; their work should be read by anyone interested in the pharmacologic, as opposed to the flow cytometric, aspects of dye probes of cell membrane potential. It is also evident from the work of Chen's group that thiocyanine dyes are more toxic than indo- and oxocyanines<sup>1683</sup>.

Since the late 1980's, a lot of interesting things have happened in the mitochondrial area, with flow cytometry playing a pivotal role.

Borth, Kral, and Katinger<sup>1699</sup> established that R123 fluorescence of hybridomas was responsive primarily to glucose concentration, rather than to aging or growth; this was significant since R123 fluorescence was proposed as a useful parameter that has been proposed for use in monitoring cells in bioreactors. Myc et al<sup>1700</sup> used Hoechst 33342 and R123 to determine that there was no variation with phases of the cell cycle in R123 retention characteristics in either normal lymphocytes or leukemic cells.

Irion et al<sup>1706</sup> and Rottele and Zimmermann<sup>1707</sup> studied the kinetics of uptake of a variety of dyes with different lipophilicities into HeLa cell mitochondria *in situ*. The kinetics of uptake were found to be limited by diffusion; more lipophilic molecules were taken up more rapidly. Dye molecules accumulated in strongly lipophilic areas of the mitochondria, and both the potential gradient and hydrophobic interactions contribute to strong dye binding. Styrylpyridinium dyes are of interest because, unlike cyanines, they exhibit very low fluorescence in aqueous solution.

### The Search for Better $\Delta\Psi_m$ Probes: Round One

Maftah et al<sup>1696</sup> and others<sup>1697-8</sup> described the use of **nonyl acridine orange (NAO)**, which they reported stained mitochondria in a membrane potential-independent fashion. One of the problems with attempting to measure  $\Delta\Psi_m$  using the fluorescence of R123 or other dyes is that the number and size, or mass, of mitochondria vary from cell to cell; it is therefore not possible to determine to what extent differences in dye fluorescence between cells reflect differences in  $\Delta\Psi_m$ , as opposed to differences in these other factors. In theory, NAO fluorescence would provide a measurement of mitochondrial mass. Since the fluorescence emission maxima of NAO and R123 are quite close to one another, it would not be feasible to attempt ratiometric measurements. However, I suggested in the previous edition that the ratio of

fluorescence of a suitably spectrally separated cationic dye, e.g., DiIC<sub>1</sub>(5) and NAO might provide an indicator of  $\Delta\Psi_m$  normalized for differences in mitochondrial mass; I was wrong. I also speculated that the nonyl group locked NAO into the mitochondrial membrane, and it looks as if I was right about that; I can't finish the story without bringing in some other developments.

O'Connor et al used flow cytometry with rhodamine 123<sup>1703</sup> and other dyes<sup>1704</sup> to analyze isolated individual mitochondria; staining with R123, safranin O, and DiOC<sub>6</sub>(3) were potential dependent, while staining with NAO was not, as would be expected. Wolf and Kapatso<sup>1705</sup> were able to discriminate isolated neuronal synaptosomes from free mitochondria because, under the experimental conditions used, the former maintained a membrane potential and the latter did not.

Juan et al<sup>2310</sup> described a kinetic measurement procedure using rhodamine 123 to assess mitochondrial membrane potential; they found that, if dye and cell concentrations were kept constant, the rate of uptake of R123 by isolated rat hepatocytes was relatively constant, with increasing concentrations of added glucose or other substrates increasing the dye uptake rate and addition of uncouplers decreasing the dye uptake rate.

Hahn et al<sup>1702</sup> described a photocrosslinking fluorescent indicator of mitochondrial membrane potential; a carbocyanine dye was derivatized with a photoreactive nitrophenylazide group so that illumination would covalently attach it to nearby molecules. The dye, **PhoCy** (photofixable cyanine), specifically stained mitochondria in living fibroblasts; when stained cells were illuminated and fixed with formaldehyde, staining was retained owing to cross-linking, while fixation without illumination eliminated mitochondrial staining. If the mitochondria in cells were energized in the first place, one could, in theory, label them with PhoCy, wash out excess dye, lock the PhoCy into the mitochondria by illuminating the cells, apply some treatment, and restrain with a spectrally distinct cationic dye to determine whether or not  $\Delta\Psi_m$  had decreased. However, PhoCy itself apparently didn't make it to market, although some other reactive cationic mitochondrial dye probes eventually did.

### $\Delta\Psi_m$ , JC-1, and Apoptosis

Lan Bo Chen published two reviews, in 1988<sup>1694</sup> and 1989<sup>1695</sup>, reflecting what he and his coworkers had done with R123 and other dyes up to that point. In 1991, his group described the use of the symmetric cyanine dye 5,5',6,6'-tetrachloro-1,1',3,3'-tetraethylbenzimidazolocarbo-cyanine iodide (**JC-1**), which forms fluorescent aggregates, as a probe of mitochondrial membrane potential<sup>1681-2</sup>. When excited at 490 nm, JC-1 monomers show an emission maximum at 527 nm, while aggregates emit maximally at 590 nm. In theory, the orange to green fluorescence ratio should give you a measure of membrane potential.

I've tried JC-1 in cells and bacteria; the biggest problems I've found with it is that it aggregates in solution and that it

takes much longer to equilibrate to stable fluorescence values than do the more popular dyes such as DiOC<sub>6</sub>(3) and DiOC<sub>6</sub>(3). The fluorescence distributions in two dimensions are broad enough so that taking ratios doesn't help all that much. There are probably better dyes out there with similar properties if you want to do ratiometric measurements, but looking at two-color fluorescence from JC-1 has turned out to be very useful, even if it won't let you measure  $\Delta\Psi_m$  to the nearest millivolt.

Chen's group and collaborators<sup>108</sup>, using NMR, found that R123 had different effects on intermediary metabolism of normal and cancer cells. On another front, the report by Chen's group<sup>682</sup> that membrane potentials were different based on differences in JC-1 fluorescence at different points in mitochondria resonated with the conclusion drawn by Skulachev and his colleagues, based on analyses of fibroblast and cardiac myocyte mitochondria<sup>109</sup> and on filamentous cyanobacteria<sup>1710</sup>, that networks of mitochondria (or bacteria) act as power-transmitting protonic cables, with membrane potential changes propagating along the network<sup>1711</sup>. A cellular information superhighway? For what it's worth, Bedlack, Wei, and Loew<sup>1712</sup> observed localized membrane depolarizations that they believed to be involved in electric field-directed neurite growth. This gets us from subcellular power transmission lines to the kind a lot of people worry about these days; it's not at all illogical that electric field effects would be mediated via membrane potential changes, but I haven't seen anything along this line hit the newspapers yet. I haven't looked that hard at the journals. Chen's group published a methods paper and review on JC-1 in 1995<sup>2810</sup>, but things didn't get really interesting until after that.

In 1993, Cossarizza et al<sup>1701</sup> reported using JC-1 for two-color flow cytometric measurement of mitochondrial membrane potential; while, as I said, it didn't give them values to the nearest millivolt, it did (and does) a much better job of discriminating cells with energized and deenergized mitochondria than did other popular dyes<sup>2811</sup>.

In 1993, Richter<sup>2812</sup> suggested that maintenance of  $\Delta\Psi_m$  was important in preventing apoptosis; in 1994, Cossarizza et al<sup>2813</sup> and Vayssiere et al<sup>2814</sup> reported that  $\Delta\Psi_m$  was reduced in apoptosis, and, in 1995, Cossarizza et al<sup>2815</sup> reported that N-acetylcysteine stabilized  $\Delta\Psi_m$  and prevented apoptosis in cells treated with agents that would normally induce the process. Richter and Cossarizza et al joined forces on a 1996 paper emphasizing the role of maintenance of  $\Delta\Psi_m$  and ATP production in the prevention of apoptosis. The concept, and JC-1, started to get a lot of attention from that point on; I'll have more to say about the subject when I discuss apoptosis in Chapter 10. Meanwhile, I'll continue with the story of mitochondrial probes.

### The Search for Better $\Delta\Psi_m$ Probes: Round Two

While, by 1997, JC-1 was recognized as more reliable in providing information on the state of energization of mitochondria than either DiOC<sub>6</sub>(3) or R123<sup>2811</sup>, it did not provide a quantitative measure of  $\Delta\Psi_m$ , at least when applied to

whole cells. Rottenberg and Wu<sup>2817</sup> noted in 1997 that DiOC<sub>6</sub>(3) itself induced apoptotic changes in lymphocytes from old mice, which led them to consider some attributes of this and other dyes that might affect their use as probes of  $\Delta\Psi_m$ , and, in 1998, to report that DiOC<sub>6</sub>(3) could be used for quantitative flow cytometric measurements of  $\Delta\Psi_m$ <sup>2818</sup>.

It had been known for some time that DiOC<sub>6</sub>(3) and other oxacarboxyanine dyes inhibited NADH reductase in isolated mitochondria *in vitro*; Rottenberg and Wu reasoned that mitochondria *in situ* would be affected by substantially lower concentrations of dye in solution, because of the Nernstian and non-Nernstian concentration that occurs in cells. They found that the respiration of lymphocytes exposed to 40-100 nM DiOC<sub>6</sub>(3), a range of concentrations commonly used for assessment of was inhibited approximately 90 percent, suggesting that the probe itself was likely to alter the parameter they were trying to measure.

Apart from their effect on respiration and  $\Delta\Psi_m$ , extracellular dye concentrations in the 40-100 nM range create problems because, as mentioned on pp. 388 and 395, the concentration of dye in energized mitochondria can easily reach 10,000 times the extracellular dye concentration, and, at intramitochondrial concentrations in the 400-1000  $\mu$ M range, the fluorescence of dye in mitochondria should be almost completely quenched.

I noted, in the discussion of measurements of cytoplasmic membrane potential, that DiOC<sub>6</sub>(3) fluorescence in cells, measured by flow cytometry, becomes independent of membrane potential at an extracellular dye concentration of 2  $\mu$ M. I also noted that membrane potential changes in cells exposed to that concentration of dye can be measured in cuvettes, because the cuvette measurement measures the fluorescence of free dye in solution. In order to keep cellular fluorescence responsive to changes in cytoplasmic membrane potential, it is necessary to use lower concentrations of dye than might be used for cuvette measurements, and the 10-100 nM concentrations typically used for flow cytometry may be advantageous in terms of eliminating much of the effect of  $\Delta\Psi_m$  on cytoplasmic membrane potential by virtue of extensive quenching of intramitochondrial dye.

When we are trying to measure  $\Delta\Psi_m$  by flow cytometry, we cannot practically distinguish between fluorescence from intramitochondrial dye and fluorescence from dye in the extramitochondrial portions of the cell. We would prefer to have a monotonic relationship between measured fluorescence and  $\Delta\Psi_m$ ; the fluorescence intensity measured from cells with energized mitochondria should be greater than that measured from cells with deenergized mitochondria, and cells with intermediate values of should yield intermediate values of fluorescence intensity. This is unlikely to happen when there is extensive quenching of dye in mitochondria; it is far more likely that a decrease in  $\Delta\Psi_m$ , resulting in release of dye into the cytosol, will lead to an increase in cellular fluorescence. Rottenberg and Wu<sup>2818</sup> found that 0.2 nM DiOC<sub>6</sub>(3) provided a monotonic fluorescence response across the range of  $\Delta\Psi_m$ .

Since the concentrations of JC-1 typically used for studies of  $\Delta\Psi_m$  are in the range between 1 and 10  $\mu\text{M}$ , it is not unlikely that perturbation by the dye will complicate any attempt to derive a quantitative measurement. Because the response of JC-1 to  $\Delta\Psi_m$  is largely dependent on the concentration of dye being high enough to promote formation of J-aggregates, it is likely that reducing the concentration to the nanomolar range would eliminate the metachromatic fluorescence response that has provided most of the motivation for using the dye. Cossarizza et al<sup>2819</sup> did find a linear relationship between JC-1 orange (590 nm) fluorescence and  $\Delta\Psi_m$  in isolated mitochondria, but it is likely that the intramitochondrial dye concentration in that experimental situation was lower than would be expected in mitochondria *in situ* due to the absence of the Nernstian and non-Nernstian concentration of dye into a cytoplasmic extramitochondrial compartment.

In 1996, Poot et al<sup>2820</sup>, at Molecular Probes, described two reactive probes that responded to  $\Delta\Psi_m$ , **chloromethyl-X-rosamine (CMXRos)** and **CM-H<sub>2</sub>XRos**, both given the **MitoTracker Red** trade name. Both probes are lipophilic and cationic, and are concentrated in mitochondria, where the chloromethyl groups on the probes bind covalently to thiols. CMXRos is fluorescent; its excitation maximum is at 578 nm, but some fluorescence is excitable at 488 nm. The emission maximum is at 599 nm. CM-H<sub>2</sub>XRos, the reduced form of CMXRos, is nonfluorescent; once inside cells with an active energy metabolism, it is oxidized to CMXRos.

The ability of these probes to bind covalently to constituents of mitochondria allows them to withstand fixation, as did the PhoCy dye described on p. 397, but there has been a running controversy in the literature as to how faithfully CMXRos measurements of fixed cells represent the state of mitochondrial energization before fixation. In dual staining experiments, Macho et al<sup>2821</sup> found CMXRos fluorescence to be highly correlated with DiOC<sub>6</sub>(3) fluorescence, and pursued immunofluorescence measurements of intracellular proteins such as Bcl-2 in cells that had been fixed and permeabilized following CMXRos staining. Ferlini et al<sup>2822</sup> questioned whether some of the correlation between CMXRos and cyanine dye fluorescence represented spectral crosstalk, but Macho et al<sup>2823</sup>, in response, cited additional evidence that CMXRos responded to  $\Delta\Psi_m$ .

Molecular Probes offers several fixable mitochondrial probes in addition to CMXRos and CM-H<sub>2</sub>XRos; these include **MitoTracker Green FM**, which has spectral characteristics similar to fluorescein but is almost nonfluorescent in aqueous solution, and **MitoTracker Orange CM-H<sub>2</sub>TMRos** and **CMTMRos**, which emit at 576 nm<sup>2824</sup>. Hollinshead et al<sup>2824</sup>, in a paper demonstrating the advantages of antibiotin antibodies, which react with endogenous biotinylated proteins in mitochondria, for specific labeling of those organelles in fixed material, reported that MitoTracker Green FM staining, representative of the state of mitochondrial energization before fixation, was preserved in fixed tissue. Poot and Pierce<sup>2825</sup> reported that, in cells stained

with 200 nm each of MitoTracker Green FM and CMXRos, the ratio of CMXRos fluorescence to MitoTracker Green fluorescence provided better discrimination of apoptotic cells than did CMXRos fluorescence alone. A challenge by Gilmore and Wilson<sup>2826</sup> was followed by a response to Ferlini et al by Poot and Pierce<sup>2827</sup>, maintaining that changes in CMXRos fluorescence are sensitive indicators of early apoptosis. Salvioli et al<sup>2828</sup>, in a study of HL-60 cells, conceded that, while JC-1 and CMXRos did not always give identical results, CMXRos was a reliable probe for assessing  $\Delta\Psi_m$ , but Mathur et al<sup>2829</sup>, studying cultured cardiomyocytes, found that JC-1 staining did reflect  $\Delta\Psi_m$ , but that CMXRos staining did not.

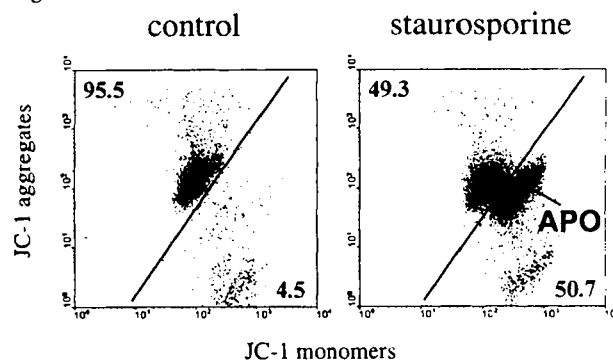

Figure 7-31. Demonstration of apoptotic HL-60 cells (APO) with deenergized mitochondria by JC-1 staining. Apoptosis was induced by staurosporine. The “JC-1 aggregates” axis displays 590 nm fluorescence; the “JC-1 monomers” axis displays 530 nm fluorescence. From: Salvioli et al, *Cytometry* 40:189-197, 2000 (Reference 2828), © John Wiley & Sons, Inc., used by permission.

If you decide to be conservative and rely on JC-1 as your probe for  $\Delta\Psi_m$ , Figure 7-31, above, gives you an idea of what you can expect. The apoptotic cells contain somewhat fewer JC-1 aggregates, as indicated by slightly lower 590 nm fluorescence, and substantially more JC-1 monomers, as indicated by 530 nm fluorescence, than do the unaffected or control cells. It would not be unusual to see lower values of 590 nm fluorescence in apoptotic cells than are shown in this figure.

In 2000, Keij et al<sup>2830</sup> reported that mitochondrial staining by NAO (p. 397), MitoTracker Green, and another Molecular Probes offering, **MitoFluor Green**, was affected by  $\Delta\Psi_m$  changes induced by drugs prior to staining. A critique by Isola et al<sup>2831</sup> noted that most people stained first and applied treatments later. However, Keij et al have made the point that the mitochondrial uptake of all of the dyes they used is potential-dependent, which should bring us closer to the conclusion that neither NAO nor any of the MitoTracker dyes is a probe of “mitochondrial mass.”

It had been alleged for many years that NAO binding to mitochondria was at least partly potential-independent, and reflected the affinity of the dye for **cardiolipin**, a polyunsaturated acidic phospholipid found exclusively in bacterial and mitochondrial membranes. NAO has, therefore, been

used as a probe for cellular cardiolipin content as well as a probe for mitochondrial mass; Jacobson et al<sup>2832</sup>, who have confirmed that NAO binding responds to  $\Delta\Psi_m$ , as Keij et al<sup>2840</sup> reported, may have slain that dragon. Or maybe not. Rhodamine 123 had magical properties attributed to it for years before JC-1 came along, but the mitochondrial staining properties of both dyes are largely deducible from their lipophilicities, structures, and association constants. We know that the MitoTracker dyes stay in mitochondria because they bind covalently once they are driven in by cytoplasmic and mitochondrial membrane potential gradients and by lipophilicity, and we can be pretty sure that NAO, once driven in by the same factors, is locked into mitochondrial membranes by its tracking dye-like nonyl side chain. If you're looking for a mitochondrial mass probe, anti-biotin antibodies<sup>2824</sup> may not be a bad bet.

That's about it for mitochondria; I should mention that Pham et al<sup>12765</sup> have developed a neat technique for looking at the activity of individual components of the respiratory chain in digitonin-permeabilized cells, using either 40 nM DiIC<sub>1</sub>(5) or 90 nM CMXRos as a probe of  $\Delta\Psi_m$ , and simultaneously detecting reactive oxygen species with carboxy-DCF (p. 379).

### Bacterial Membrane Potentials

**Bacteria**, unlike eukaryotes, do not compartmentalize their respiratory enzymes inside mitochondria; the enzymes are, instead, located on the inner surface of the cytoplasmic membrane. As a result, the 100-200 mV, inside-negative, potential gradient generated by bacterial energy metabolism exists across the cytoplasmic membrane, and some bacteria stain in more or less the same potential-dependent fashion with rhodamine 123, cyanine dyes, and other fluorescent lipophilic cationic dyes<sup>856-7</sup>. Other bacteria, however, have to be coaxed into staining. In general, there's not much of a problem getting **Gram-positive** bacteria to take up lipophilic dyes, because the dyes readily get through the bacterial cell wall. The **Gram-negative** bacteria are more of a problem; the lipopolysaccharide-containing **outer membrane**, really a cell wall and not a membrane, efficiently excludes lipophilic compounds. It is possible to render the outer membrane permeable to lipophilic materials using any one of a number of chemical agents; the most widely used is probably **ethylene diamine tetraacetic acid (EDTA)**, which removes calcium from the structure.

Since bacterial membrane potential changes rapidly in response to the availability or lack thereof of suitable energy sources, and is rapidly dissipated when the organism is killed by drugs or other agents, it is possible to exploit this parameter and potential-sensitive dyes in rapid cytometric procedures for bacterial detection, identification, and antibiotic susceptibility testing. This subject will be further discussed in Chapter 10; here, I will consider some particular problems in bacterial membrane potential measurement, and describe at least one possible solution.

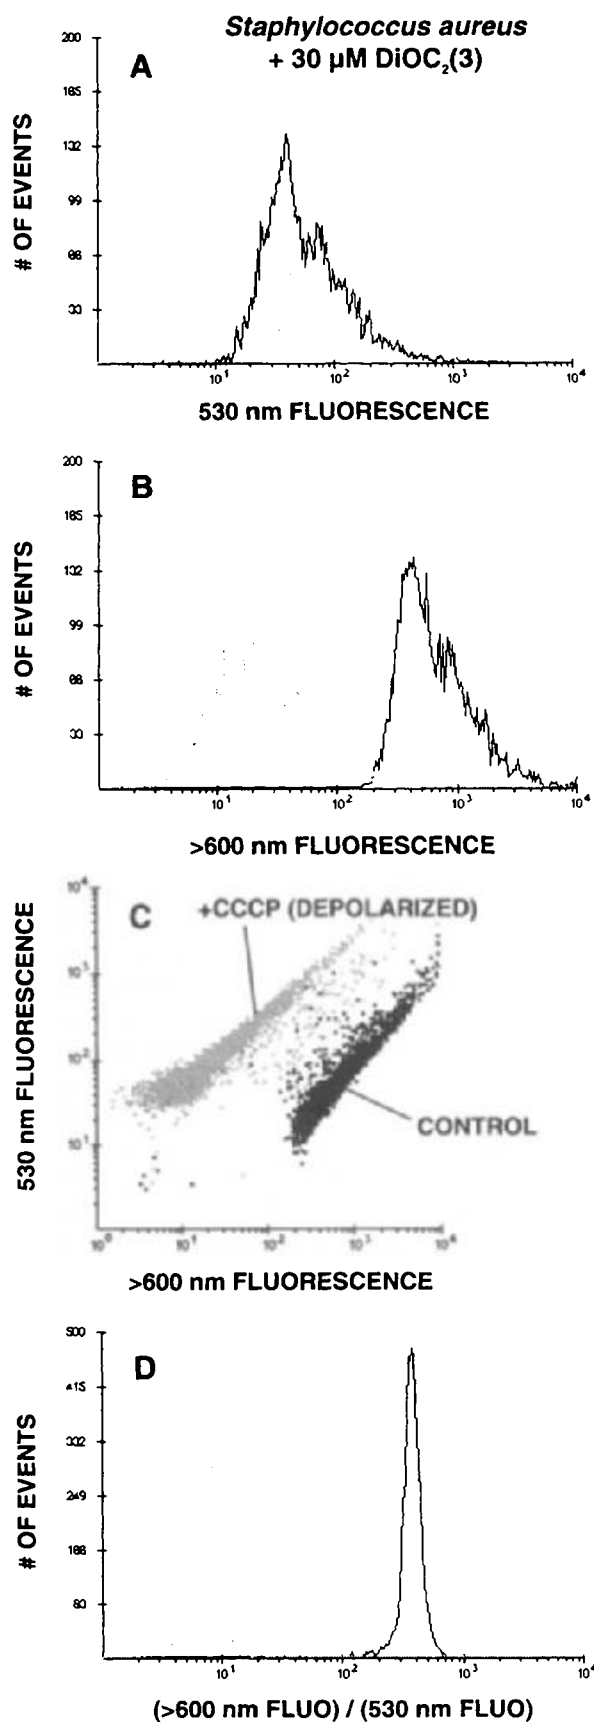

Figure 7-32 (legend on next page)

Figure 7-32 (opposite page). Measurement of the membrane potential of *Staphylococcus aureus* using DiOC<sub>2</sub>(3) and a ratiometric technique developed by Novo et al.<sup>2357</sup>. Cells are loaded with 30 μM dye, and fluorescence, excited at 488 nm, is measured at 530 nm and at >600 nm. The curves and dots plotted in gray represent cells depolarized with CCCP; the curves and dots plotted in black represent control cells. Plots were created with FCS Express software (DeNovo Software).

### Ratiometric ΔΨ Measurement in Bacteria

There are now a substantial number of papers in the literature (see Chapter 10 for references) describing flow cytometric measurement of ΔΨ in bacteria, both as a means of determining the metabolic state of bacteria in their natural environments and as a means of assessing response to antimicrobial agents or lack thereof. Rhodamine 123, DiOC<sub>6</sub>(3), and the oxonol dye DiBAC<sub>4</sub>(3) have all been used as probes, and they all share a disadvantage which can be appreciated from panels A and B of Figure 7-32 and from Figure 7-27 (p. 388). The distributions of dye fluorescence from cells that are maintaining normal membrane potential and from cells that have been completely depolarized by an ionophore (gramicidin A or CCCP) overlap enough so that one cannot clearly discriminate depolarized from control cells. This becomes a serious problem when one is attempting to determine whether bacteria will respond to a drug; killing 95 percent, or even 99 percent, of the population isn't good enough.

A few years back, David Novo, now known as the entrepreneurial genius behind **DeNovo Software** and its flagship product **FCS Express**, but then fresh out of college, came to my lab and did a creditable imitation of a very good postdoc. Dave wanted to develop a flow cytometric antimicrobial susceptibility test, and we started looking at cyanine dye fluorescence in *Staphylococcus aureus*, which, while otherwise fairly user-friendly, grows in clumps. This creates even more of a problem than there is with most other bacteria when you look at fluorescence distributions, because fluorescence from a clump of  $n$  cells is  $n$  times as bright as fluorescence from a single cell. In work with oxacarboxyanines some years back, I had noted that there was a fair amount of fluorescence detectable from these dyes at wavelengths above 580 nm, and Dave followed up on these observations with some rigorous spectrofluorimetric analyses that established that, at very high concentrations, the DiOC<sub>*n*</sub>(3) dyes developed a second emission peak at around 610 nm. The concentration dependence suggested that the long-wavelength fluorescence comes from J-aggregates.

In order to get substantial emission above 600 nm from microorganisms, we had to use much higher dye concentrations than we or anyone else had used previously; the concentration we found suitable for the most tractable of the dyes, DiOC<sub>2</sub>(3), was 30 μM. When we loaded bacteria with dye at this concentration, we found that 530 nm fluores-

cence from the organisms (panel A of Figure 7-32) no longer changed significantly with ΔΨ, but that fluorescence above 600 nm (panel B of Figure 7-32) did. Both 530 nm and >600 nm fluorescence signals appeared to be sensitive to cell (or clump) mass or size, and a dot plot (panel C of Figure 7-32, also shown in color on the back cover) showed high degrees of correlation between the two fluorescence values in clusters of depolarized and control cells, with the two clusters clearly separated. It thus came as no surprise to us that the ratio of

$$(>600 \text{ nm fluorescence}) / (530 \text{ nm fluorescence}),$$

multiplied by an appropriate constant to get it on the display scale, could serve as a measure of ΔΨ. This quantity is plotted in panel D of Figure 7-32, and it is clear that the degree of overlap between values of the ratio measured in depolarized and control cells is extremely small.

By examining valinomycin-treated organisms in buffers containing a range of potassium concentrations (distributions are shown on the back cover), the fluorescence ratio measurement can be calibrated to read out values of ΔΨ; we found that the usable range for *S. aureus* ran from approximately -30 mV to approximately -130 mV.

As far as I know, the ratiometric technique we described remains the most accurate and precise flow cytometric method for measurement (we've gone beyond estimation) of bacterial ΔΨ. The details may be found in reference 2357; I should, however, add a few things we have learned since that paper was published.

The technique can be applied to Gram-negative bacteria if EDTA is used to permeabilize the outer membrane, but, while it did provide the same large degree of separation of clusters of depolarized and control cells as we noted when working with Gram-positive organisms, we were unable to construct a calibration curve because the valinomycin-potassium buffers tended to lyse the EDTA-treated Gram-negative organisms.

We examined a number of indocarbocyanine, indodicarbocyanine, thiocarbocyanine, and thiodicarbocyanine dyes and did not find one that exhibited sufficient long wavelength fluorescence at high concentrations to permit its use for ratiometric measurements. The Molecular Probes dye JC-9<sup>2332</sup>, a dibenzo homologue of DiOC<sub>2</sub>(3) that shares the tendency of JC-1 to form fluorescent J-aggregates, can be used for ratiometric measurements but the fluorescence ratio distributions obtained from control and depolarized bacteria stained with JC-9 are not as well separated as those obtained from bacteria stained with DiOC<sub>2</sub>(3). In our hands, JC-1 itself has not been usable for ratiometric measurements of ΔΨ in bacteria.

I suspect that DiOC<sub>2</sub>(3) could be used for ratiometric membrane potential measurement in isolated mitochondria, however, at the concentration necessary to produce a substantial fraction of J-aggregates, it is likely to perturb mitochondrial function<sup>2818</sup>.

In the paper<sup>235</sup>, we reported that we were unable to grow bacteria after they had been exposed even briefly to 30  $\mu\text{M}$  DiOC<sub>2</sub>(3). However, Imogen Wilding of GlaxoSmithKline reports (personal communication, 2001) that it is possible to culture organisms that have been exposed to the dye at 30  $\mu\text{M}$  and at higher concentrations. I should have learned from my experience with pyronin Y (p. 324) that growing cells is not my strong point.

It is worth thinking about why this particular ratiometric method works so well in bacteria. I used to use cyanine dye fluorescence for  $\Delta\Psi$  estimation, working with an external concentration of no more than 100 nM. Assuming that  $\Delta\Psi = -122$  mV, which would make the intracellular dye concentration 100 times the extracellular concentration according to the Nernst equation, and adding another factor of 10 for non-Nernstian effects that increase intracellular dye concentration, we come up with an intracellular concentration of 100  $\mu\text{M}$ , which sounds very impressive, until we consider two other factors. First, the volume of the bacterial cell is only about 1 fL, and the word from Avogadro is that, given that intracellular concentration, we will only find about 60,000 molecules of dye in the organism. Second, most of those molecules are likely to be quenched, meaning that the quantum efficiency will not be on the order of 0.5, which is not atypical for cyanine dyes in nonpolar solvents, but is more likely to be a tenth of that value or less, so it will take at least ten molecules of intracellular dye to give us one MESF worth of fluorescence, leaving us with no more than 6,000 MESF. If we assume that the Q value (p. 222) for detecting a cyanine dye is similar to that for detecting fluorescein (.012 photoelectrons/MESF), we'll generate one photoelectron for every 80 MESF, or 75 photoelectrons for 6,000 MESF. If photoelectron statistics were the only source of variance in the fluorescence distribution, the CV would be no lower than 11.4 percent. The ratiometric measurement method uses a dye concentration 300 times higher, and, even though we can expect there to be even more quenching of the fluorescence of intracellular dye, the photoelectron statistics should improve substantially.

The ratiometric  $\Delta\Psi$  measurement described by Gonzales and Tsien<sup>246,2808,9</sup> (p. 392), using a labeled fatty acid or tracking dye and an oxonol, could, in principle, be applied to bacteria, but since one would expect there to be only a few thousand molecules of each of the dyes present per cell, it would probably be necessary to use either a slow flow system or a static or scanning cytometer to get good enough photoelectron statistics to make the exercise worthwhile.

### $\Delta\Psi$ Measurement: Cautions and Conclusions

Whether you measure cytoplasmic, mitochondrial, or bacterial membrane potential, you will end up working with some extremely lipophilic dyes. Lipophilic implies hydrophobic; these materials are almost insoluble in water and would prefer to be almost anywhere else. That's what accounts for their non-Nernstian uptake into cells, and it also makes them stick to just about any surface to which they

may be exposed while in aqueous solution. The dyes, and the ionophores used to prepare controls, which are also lipophilic, will bind to the tubing in your flow cytometer. If you don't flush the system carefully when you are finished, the dyes and ionophores will abandon the tubing for the next batch of cells that comes along. I use both chlorine bleach and alcohol to clean my system, and, when I think it is clean, I run some unstained cells through and see whether they become fluorescent during the run. If they do, I go through another cleaning cycle. As a last resort, I change all the sample tubing. That's easy to do on a Cytomutt; it may not be on your apparatus. If you use a shared instrument, it might be a good idea to check with your fellow users and the operator, if there is one, before you attempt to do ratiometric measurements in bacteria with 30  $\mu\text{M}$  cyanine dye.

When you do immunofluorescence measurements on fixed cells, you don't find that your cells have good days and bad days; when you measure membrane potential, or pH, or calcium, in live cells, you do. If the cells (or at least the control cells) aren't happy, you won't be.

You do have to be fairly obsessive-compulsive about technique to get good results. The primary papers and the protocol books I mentioned in Chapter 2 and at the beginning of this chapter are a good place to start; if you need more detail or clarification, an e-mail to an author or a posting to the Purdue Cytometry Mailing list is likely to get you the information you need.

## Optical Probes of Intracellular Calcium

### The Bad Old Days

In 1984, when the First Edition of this book was written, it wasn't clear that flow cytometry had much to contribute in the area of intracellular calcium measurements; a lot of people were interested, and the existence and importance of calcium fluxes and redistributions was obvious, but the probes weren't there. Now, they are.

The older generation of optical and alternative techniques for measurement of intracellular  $\text{Ca}^{2+}$  concentrations were discussed at length in a book by Thomas<sup>502</sup> and in review articles by Blinks et al<sup>503</sup> and Tsien<sup>504</sup>. Among the more classical optical probes of intracellular  $[\text{Ca}^{2+}]$ <sup>502,4</sup> are **aequorin**, a luminescent protein now best known because of its connection to GFP, and **arsenazo III**, a metallochromic dye, neither of which enters intact cells. Arsenazo III response to changes in  $[\text{Ca}^{2+}]$  is measured by a spectral shift detected by two-wavelength absorption measurements; this technique could conceivably be adapted to flow cytometry but cells would have to be permeabilized or microinjected to get the dye in before they could be studied.

### Chlortetracycline as a Probe of "Membrane-Bound" Calcium in Cells

Caswell and Hutchison<sup>505,6</sup> described the use of the antibiotic **chlortetracycline (CTC)** (not, I hope, likely to be confused with the tetrazolium dye with the same abbrevia-

tion (p. 379)) as a fluorescent probe of intracellular "membrane-bound"  $\text{Ca}^{2+}$ . The concept of "**membrane-bound**"  $\text{Ca}^{2+}$  arose from their finding that the fluorescence of CTC was increased when the compound was bound in hydrophobic regions, and that the fluorescence of  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  chelates of CTC was higher than that of CTC. Measurement of emission at 520 nm with excitation at 390 nm supposedly maximizes the discrimination of fluorescence emitted by molecules of CTC- $\text{Ca}^{2+}$  chelate bound in hydrophobic regions from fluorescence emitted by free CTC, bound CTC, and other chelates.

When cells equilibrated with 10-200  $\mu\text{M}$  CTC are examined under a fluorescence microscope, fluorescence is observed in the same membranous and lipid-bearing structures that are stained by cyanine dyes. If the cells are then washed and the fluorescence of a cell suspension is measured in a cuvette, a gradual decrease in fluorescence is observed as CTC is released from cells into the medium. Treatment of the cells with  $\text{Ca}^{2+}$  ionophore **A23187** or with **ligands reactive with cell surface receptors** (e.g., chemotactic peptides in the case of neutrophils<sup>447</sup>, bethanechol in pancreatic acinar cells<sup>507,8</sup>, con A in thymocytes<sup>509</sup>) causes a decrease in fluorescence, observable under the microscope as well as in a fluorometer. This is interpreted as indicating **release of  $\text{Ca}^{2+}$  from hydrophobic (membrane) binding sites**.

Flow cytometry of CTC-stained cells<sup>12</sup>, using UV or violet excitation from lasers or arc lamps, yields "haystack" fluorescence distributions with large variances, similar to those obtained from cells stained with dye  $\Delta\Psi$  probes. The distributions shift following addition of A23187 or stimulating ligands, but one cannot discriminate subpopulations of stimulated cells. Thus, single cell studies with CTC are probably better done by methods that allow sequential observations of the same cells than by flow cytometry.

Spectral studies by Mathew and Balaram<sup>510</sup> suggest that two-wavelength emission measurements of CTC fluorescence excited in the UV might yield a ratio sensitive to shifts in intracellular  $\text{Ca}^{2+}$ , which should have a narrower distribution than is observed for CTC fluorescence. Since the CTC spectrum is sensitive to pH changes in the physiologic range, however, which may also occur during cell activation, results might be difficult to interpret.

### Probes for Free Cytoplasmic Calcium: Quin-2

The first probe to come into vogue for studies of **free cytoplasmic  $[\text{Ca}^{2+}]$**  was **quin-2**, first introduced by Tsien and his associates.<sup>304,511-8</sup> This material is an extremely selective calcium chelator that is introduced into cells as an inactive ester that yields reactive quin-2 after enzymatic hydrolysis. Quin-2 is UV-excited (334-337 nm is the favored wavelength region) and blue fluorescent (maximum emission from the intracellular  $\text{Ca}^{2+}$  chelate is at about 490 nm). However, the fluorescence emission from the amount of quin-2 that can be gotten into a cell is pretty weak, generally no more than 10 times the level of cellular autofluorescence (in the spectral regions applicable to quin-2 excitation and

emission measurement, this is generally pyridine nucleotide autofluorescence). The  $\text{Ca}^{2+}$  chelate is about 7 times as fluorescent as the uncomplexed dye.

Quin-2 has been used for bulk measurements of cells in cuvettes and for single-cell measurements by microphotometry; it has been possible using either method to demonstrate rises in cytoplasmic  $[\text{Ca}^{2+}]$  that occur within seconds following receptor stimulation or ionophore addition and which abate within a few minutes thereafter. The extremely high affinity of quin-2 for  $\text{Ca}^{2+}$  results in considerable perturbation of  $\text{Ca}^{2+}$  metabolism in quin-2-loaded cells and tissues; I have heard of the dye stopping hearts and triggering mitosis in lymphocytes. I also heard that some preparations of quin-2 yielded 10 or 12 spots on chromatography.

Even without its toxicity or impurities, quin-2 is not well suited for use with most flow cytometers because the absorption of the  $\text{Ca}^{2+}$  chelate is extremely low at the wavelengths above 350 nm at which most ion laser and arc lamp sources are operated for UV excitation. Better excitation wavelengths are available from arc lamps, krypton lasers (a very weak line at 337 nm) and from He-Cd lasers. I have used the 325 nm line from a He-Cd laser for quin-2 fluorescence excitation, which allows demonstration of an ionophore-induced  $[\text{Ca}^{2+}]$  transient by a shift in the position of a fluorescence distribution. The distribution itself, however, is a haystack, making it unlikely that a small number of activated cells within a heterogeneous population could be discriminated by flow cytometry using quin-2.

For microphotometric and cinefluorometric studies in which fluorescence from the same cells or tissues was measured repeatedly, quin-2 did not have the same disadvantages as for flow cytometry, and the probe provided investigators with a substantial amount of information about cytoplasmic  $[\text{Ca}^{2+}]$  changes before Roger Tsien and his colleagues cooked up two much better reagents, **fura-2** and **indo-1**<sup>538</sup>.

### Fura-2 and Indo-1: Ratiometric $\text{Ca}^{2+}$ Indicators

Like quin-2, fura-2 and indo-1 are selective calcium chelators; since neither compound has as high an affinity for calcium as does quin-2, the newer probes do not perturb cellular calcium metabolism to anywhere near the extent to which quin-2 does. Also like quin-2, both fura-2 and indo-1 are typically introduced into cells in the form of acetoxy-methyl (AM) esters, which are enzymatically hydrolyzed in cells to the free dyes. Cells are loaded by incubation with 1-15  $\mu\text{M}$  concentrations of AM ester for 30-90 min at 37 °C; in some cases, an agent such as a Pluronic detergent may be needed to improve penetration of cells by the dye<sup>339</sup>.

Both fura-2 and indo-1 are at least ten times as fluorescent as quin-2, and the newer dyes also share the desirable characteristic, absent in quin-2, of undergoing substantial **spectral shifts** upon binding calcium. In the case of fura-2, the most pronounced change is in the excitation spectrum; while, **for indo-1, the emission spectra of the free dye and the calcium chelate differ substantially**, as shown in Figure 7-9 (p. 296) and Figure 7-33 (next page). Fura-2 and

indo-1 can, therefore, both be used to make **ratiometric** measurements of cytoplasmic  $[Ca^{2+}]$ , which cancel out many extraneous factors, including the effect of cell-to-cell variations in dye content.

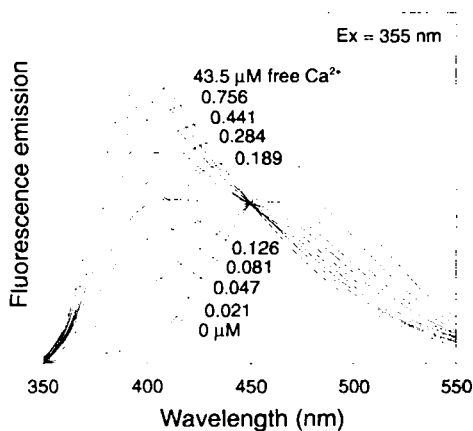

Figure 7-33. Emission spectra of indo-1 in solutions of increasing free calcium ion concentration. The figure was provided by Molecular Probes.

**Fura-2** has an emission maximum at 510 nm; the absorption maximum for the calcium chelate is at about 335 nm and that for the free dye is at about 362 nm. If fluorescence at 510 nm is measured, first using 340 nm excitation and then using 380 nm excitation, the ratio ( $F_{340 \rightarrow 510} / F_{380 \rightarrow 510}$ ) provides a measure of cytoplasmic  $[Ca^{2+}]$ . The excitation wavelengths used for fura-2 measurements are readily available from xenon arc lamp sources, which do not have sharp spectral peaks in the near UV and visible regions, and fura-2 has been used for single cell  $[Ca^{2+}]$  studies employing microspectrophotometers and video microscopes<sup>859-61</sup>. Fura-2 is less well suited for use in flow cytometers, because the excitation wavelengths are not readily obtained from the standard laser or arc sources.

**Indo-1** fluorescence is excited by UV light; the free dye shows maximum emission at about 480 nm, and the calcium chelate emits maximally at about 405 nm. Any of the UV excitation sources commonly employed in flow cytometry can be used to excite indo-1, including He-Cd (325 nm), argon (351/363 nm) and krypton (350/356 nm) lasers and Hg arc lamps (366 nm). Fluorescence is measured through 10-20 nm bandpass filters centered near 405 and 480 nm, although I have been told by various people that they prefer 500 or even 520 nm filters to 480 nm filters for the longer wavelength measurement. The ratio, i.e., ( $F_{UV \rightarrow 405} / F_{UV \rightarrow 480}$ ), is taken as a measure of cytoplasmic  $[Ca^{2+}]$ <sup>862</sup>. An example of flow cytometric measurement of cytoplasmic  $[Ca^{2+}]$  changes in cell activation appears in Figure 7-21 (p. 365).

Since quin-2 provided only poor resolution of responding and nonresponding cell subpopulations<sup>864</sup>, it was not widely used in flow cytometry. Indo-1, however, came into considerable vogue in a relatively short time after its properties were first described<sup>853,865</sup>. A particularly useful technique

described by Rabinovitch et al<sup>866</sup> employs **indo-1 in combination with fluorescent antibodies** to follow cytoplasmic  $[Ca^{2+}]$  responses in cell populations defined by the presence of a specific surface antigen.

While ratiometric  $[Ca^{2+}]$  measurements made with either fura-2 or indo-1 eliminate the effect of cell-to-cell variations in dye content, measurements made with indo-1 have an additional advantage in that the effects of uneven illumination and of light source noise also are eliminated by virtue of their equal influences on the numerator and denominator of the ratio. This advantage, it should be noted, is common to other flow cytometric ratio measurements in which both parameters used in the ratio are measured at the same time in the same beam.

If aliquots of fura-2 or indo-1 loaded cells are placed in solutions with various known  $Ca^{2+}$  concentrations and treated with a **calcium ionophore** such as **A23187** or **ionomycin**, it is possible to calibrate the fluorescence ratio measurement to yield accurate molar values of cytoplasmic  $[Ca^{2+}]$ . Kachel et al<sup>1713</sup> have described a general method for calibration of flow cytometric wavelength shift fluorescence measurements based on pulse modulation of the excitation source in a flow cytometer; it is not clear how readily this can be implemented in existing apparatus.

Indo-1 is widely used, at least by people with UV excitation sources in their flow cytometers<sup>1714-8</sup>. Since there are probably more than 10,000 fluorescence flow cytometers out there that don't have UV sources, that's small comfort. Luckily, there are alternatives.

### Fluo-3 and Other Visible-Excited $Ca^{2+}$ Probes

In 1989, Minta, Kao, and Tsien<sup>1719</sup> described a series of fluorescein- and rhodamine-based calcium indicators suitable for use with 488 nm excitation. The most widely used of these is **fluo-3**, which has the spectral characteristics of fluorescein, but which is almost nonfluorescent unless bound to calcium. The emission spectrum of fluo-3 at various values of  $[Ca^{2+}]$  is shown in Figure 7-34 (next page).

Unlike fura-2 and indo-1, fluo-3 does not exhibit a spectral shift with changes in calcium concentration. A fluo-3 fluorescence distribution is a haystack; if you're stimulating a cell population, the haystack moves to the right when the cytoplasmic  $[Ca^{2+}]$  goes up and back to the left when it goes back down. In 1990, Rijkers et al<sup>1720</sup> came up with a dodge that enables fluo-3 to be used in a more or less ratiometric mode; they load cells simultaneously with fluo-3 and with SNARF-1, a pH-sensitive dye that will be discussed in the next section. The amounts of the two dyes taken up by cells are roughly similar. The emission of SNARF-1 at 600 nm does not change appreciably during activation; as a result, the ratio of fluo-3/SNARF-1 fluorescence (520 nm emission to 600 nm emission) provides a measure of cytoplasmic  $[Ca^{2+}]$  with considerably less variance than there is in the fluo-3 histogram.

In 1994, Novak and Rabinovitch<sup>2833</sup> introduced an improved ratiometric method combining fluo-3 with another

calcium probe, **Fura Red**. Fura Red is excitable at 488 nm, emits maximally at 660 nm, and becomes less fluorescent on binding calcium; the ratio of fluo-3 to Fura Red fluorescence is therefore relatively sensitive to small changes in cytoplasmic  $[Ca^{2+}]$ .

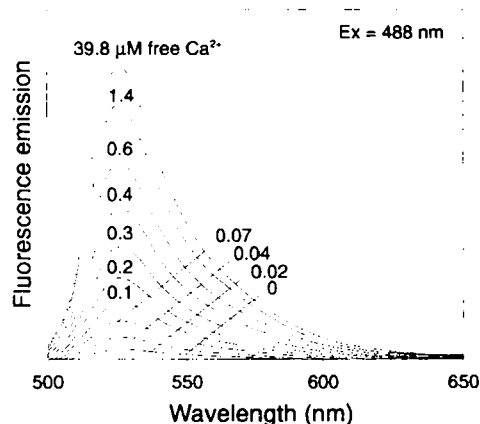

Figure 7-34. Emission spectrum of fluo-3 in solutions of increasing free  $Ca^{2+}$  concentration. The figure was provided by Molecular Probes.

Molecular Probes (see the *Handbook*<sup>2332</sup>), which offers quin-2, indo-1, fluo-3, and Fura Red, has some other visible excited calcium indicators, such as the **Calcium Green** series.

Akkaya and Lakowicz<sup>1722</sup> reported they were developing a series of styryl-based, visible-excited, ratiometric indicators, but these have apparently not hit the market yet.

I am told that, while it might be possible to make an indo-1-like calcium probe that could be excited by a UV (370 nm) diode laser, it would be difficult, if not impossible, to tweak a similar molecule sufficiently to permit excitation by a violet diode.

AM esters and dyes loaded as AM esters may be pumped out of cells; Baus et al<sup>2834</sup> reported that the anion transport inhibitor sulfapyrazone blocked the efflux of Fluo-3 from transformed murine T cells.

### Flow Cytometric Probes of Intracellular pH

Since we have all been exposed, generally starting in junior high school (that might be middle school for some of you young ones), to dyes that change color with changes in pH, it should come as no surprise that some such materials can be used for single cell analysis. If a dye changes color with pH, one can find two wavelengths at which absorption, excitation, or emission will change differently as pH changes; the pH can then be estimated from the ratio of measurements made at those two wavelengths. As we have just noted while discussing the use of fura-2 and indo-1 as calcium probes, ratiometric measurements are highly desirable, especially in flow cytometry; as we shall shortly see, ratiometric measurements of intracellular pH by flow cytometry antedate ratio measurements of cell calcium.

The first description of a flow cytometric method for estimation of intracellular pH was published in 1979 by Visser, Jongeling and Tanke<sup>519</sup>; they measured the fluorescence of intracellular **fluorescein** produced by enzymatic hydrolysis of FDA. It is the excitation spectrum, rather than the emission spectrum, of fluorescein that shows the greatest dependence upon pH<sup>202,4,369,376</sup>. Since Visser et al did not have two-wavelength excitation capability in their flow cytometer, they estimated pH changes from changes in emission above 530 nm of cells excited at a single wavelength (488 nm).

When wavelengths above 465 nm are used for fluorescein excitation, emission intensity increases with pH; at excitation wavelengths below 465 nm, emission intensity decreases with pH. When excitation is at 465 nm, an **isosbestic point**, emission intensity is independent of pH. Visser et al noted that the average emission intensity of cells equilibrated with buffers of increasing pH increased, as would be expected, when 488 nm excitation was used; decreases in intensity with increasing pH were observed when the excitation wavelength was changed to 458 nm.

Valet et al<sup>200</sup> and Gerson<sup>201</sup> described ratiometric techniques for flow cytometric pH estimation in which the ratio of intensities of green and blue fluorescence emission from UV-excited dyes was used as a measure of pH. This ratio increases with pH. The probe used by Valet et al is **1,4-diacetoxy-2,3-dicyanobenzene (ADB)**, also called **2,3-dicyano-1,4-hydroquinone diacetate**; it is available from **Sigma**. ADB is enzymatically hydrolyzed inside cells to yield **2,3-dicyanohydroquinone (DCH)**. Gerson used the coumarin **4-methylumbelliferone (4-MU)** in free and esterified forms. These probes have an advantage over fluorescein derivatives in that they can be used with single beam excitation; 4-MU, however, also has the disadvantage of being able to cross cell membranes freely, and therefore tends to leak out of cells rapidly.

There exist **distributional radiolabel and dye probes of intracellular pH**. These are weak acids and bases that partition across membranes as a function of transmembrane pH gradients; 9-aminoacridine is an example. While they are usable for studies of cells in bulk, there is absolutely no reason to choose distributional pH probes for single cell studies, given the existence of dyes that can be used for ratiometric measurements.

The **calibration of ratiometric pH probes** is straightforward; fluorescence measurements are made of aliquots of cells suspended in high-potassium buffers at different, known pH's, and the cytoplasmic pH is made equal to the buffer pH by addition of the **proton ionophore nigericin** prior to flow cytometric measurement of emission or excitation ratios. This allows construction of a calibration curve. As is the case with the college chemistry variety of pH indicator techniques, cytometric measurements of pH will be most precise in the region of the  $pK_a$  of the indicator used.

An alternative calibration procedure was described by Chow et al<sup>2835</sup>, who adapted a method described by Eisner et al<sup>2836</sup>. Cells are suspended in solutions containing mixtures of

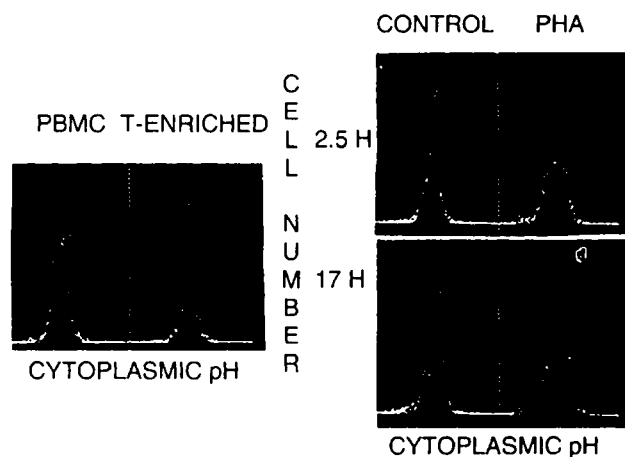

Figure 7-35. Estimation of cytoplasmic pH in human lymphocytes from carboxyfluorescein fluorescence ratio (520 nm emission; 488 and 441 nm excitation from argon and He-Cd lasers). The panel at left shows unstimulated peripheral blood mononuclear cells (PBMC) and a T cell enriched fraction. The panel at right shows control T-enriched cells and T-enriched cells exposed to PHA, 2.5 (upper pair) and 17 (lower pair) hours after exposure. PHA appears to increase pH in some cells and decrease it in others.

a weak acid (butyric acid) and a weak base (trimethylamine) in fixed ratios but different molar concentrations, allowing determination of a "pseudo null point" pH. The calibration curve is different for each cell type.

Valet et al<sup>200</sup> used ADB (DCH) primarily to demonstrate pH heterogeneity in tumor cell populations; Alabaster<sup>520</sup> employed the same probe for the same purpose. Gerson reported increases in pH within a short time following lymphocyte stimulation<sup>427</sup> and also with progression of stimulated lymphocytes through the cell cycle<sup>521</sup>; he has used bulk distributional measurements as well as flow cytometry with 4-MU and derivatives<sup>201</sup> for his analyses.

Musgrove, Rugg and Hedley<sup>868</sup> published a comparative study of 4-MU, DCH, and 2',7'-bis-(carboxyethyl)-5,6-carboxyfluorescein (BCECF)<sup>869</sup> as flow cytometric pH probes; this provides a good reference on the use of these dyes and on the calibration procedure as well. UV excitation was used for 4-MU and DCH, with pH being estimated for 4-MU from the ratio  $F_{UV \rightarrow 450} / F_{UV \rightarrow 560}$  and for DCH from the ratio  $F_{UV \rightarrow 425} / F_{UV \rightarrow 540}$ . BCECF was excited at 488 nm, and pH was estimated from the ratio  $F_{488 \rightarrow 520} / F_{488 \rightarrow 620}$ . 4-MU was poorly retained by cells; both DCH and BCECF were found to be usable over a pH range from 6.0 to 7.5. DCH gave the most sensitive indication of pH changes; BCECF was retained longest by cells. However, BCECF may be better suited to ratiometric measurements using dual-wavelength excitation than to emission ratio measurements.

Years ago, when I played the pH game briefly, I chose to pursue a flow cytometric pH estimation technique based on **fluorescein derivatives**, in preference to the probes described by Valet et al and Gerson, for several reasons. First, I wanted to be able to make **correlated measurements of pH and cell cycle position** in cells stained with Hoechst 33342, and, if possible, to measure pH and  $[Ca^{2+}]$  together in quin-2 (or indo-1) loaded cells. Both Hoechst 33342 and the calcium probes are UV-excited and blue fluorescent, and thus cannot be used with ADB or 4-MU, which share their spectral characteristics. There are no substitutes presently available for either Hoechst 33342 or indo-1 for their respective purposes. However, I already knew<sup>8</sup> that it was possible to measure Hoechst dye fluorescence and pH inde-

pendently in a three-beam flow cytometer if fluorescein derivatives were used for pH estimation.

**Carboxyfluorescein (COF)**, at the time, was the probe best suited for such studies; while its spectrum is nearly identical to that of fluorescein<sup>104,4</sup>, COF offers two significant advantages. The free dye produced intracellularly by enzymatic hydrolysis of COFDA is lost from cells much more slowly than is FDA-derived fluorescein. More important, **free COF does not enter the mitochondrial compartment**, and thus provides a good estimate of **cytoplasmic pH** rather than a composite of cytoplasmic and mitochondrial pH; BCECF shares this characteristic. In order for COFDA to enter cells, the buffer pH during loading must be kept relatively low ( $\leq 7.0$ ) to keep most of the material in an unionized form. Thereafter, pH can be restored to the physiologic (7.3-7.4) range used for most experiments. **BCECF is preferable to COF in that cells can be loaded at physiological pH.**

The pH estimate obtained from **COF or BCECF fluorescence** is derived from the ratio of emission intensities at 520-550 nm obtained using **two excitation wavelengths** above and below 465 nm. The 488 nm argon ion laser line is nearly optimal as the longer excitation wavelength. For maximum sensitivity of the emission intensity ratio to pH, the shorter excitation wavelength used should be in the 420-450 nm range; the 441 nm He-Cd laser line and the 436 nm Hg arc lamp line are both suitable for this purpose. The ratio  $F_{488 \rightarrow 530} / F_{441 \rightarrow 530}$  increases with increasing pH.

Nancy Allbritton and I (unpublished) used 488 and 441 nm excitation to make estimates of pH in human peripheral blood mononuclear cells, and in samples enriched in T cells, before and after PHA stimulation. Some of our results are shown as Figure 7-35.

The advantages of a ratio measurement are immediately apparent from the figure; this was the first "needle" distribution not representing DNA content that I had ever seen emerge from flow cytometry of real cells. The CVs of pH distributions are on the order of 5%; the displacement of peaks after lectin stimulation is at least 10%, suggesting that this parameter could be used to discriminate small subpopulations of activated lymphocytes within a few hours follow-

ing stimulation. There remains some controversy<sup>870-1</sup> as to whether pH change can serve as a litmus test for lymphocyte activation. The indicators, however, keep getting better.

Figure 7-36 shows the emission spectra of another item from Molecular Probes' copious catalog<sup>2332</sup>, the ratiometric pH indicator **carboxy SNARF-1**, which is a current favorite. This dye is well excited at 488 nm; the ratio of emission intensities at 640 and 580 nm provides a measure of pH.

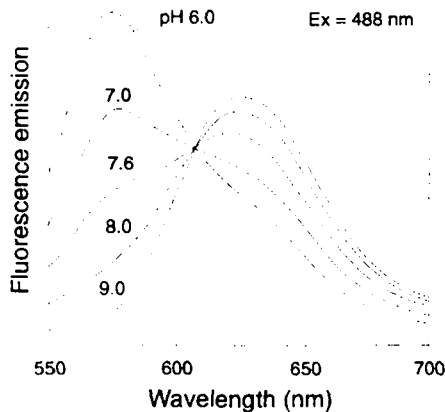

Figure 7-36. The pH-dependent emission spectra of carboxy SNARF-1 excited at 488 nm. The figure was provided by Molecular Probes.

Although some people got reasonably good results with ADB<sup>1723</sup>, by the late 1980's, BCECF had become the indicator of choice. Hedley and Jorgensen<sup>1724</sup> found an 8% CV in the BCECF fluorescence ratio obtained from B16 melanoma cells, which would correspond to 0.4 pH units; they felt, however, that much of the variance was due to instrumental factors rather than pH variation. Musgrove, Seaman, and Hedley<sup>1725</sup> used BCECF to measure pH in samples enriched for different cell cycle phases; higher pH values were associated with S, G<sub>2</sub>, and M phases of the cell cycle, with a corresponding increase in the percentage of G<sub>1</sub> cells at the lower pH range, suggesting cell-cycle dependence of pH.

Wang et al<sup>1726</sup> measured intracellular pH by the distribution of the weak acid, 5,5-dimethyl-2,4-oxazolinedione-2-<sup>14</sup>C (<sup>14</sup>C-DMO), a classical method, and by fluorescence flow cytometry with BCECF. The pH determined for CHO cells by the FCM method at external pH values of 6.0-8.1 agreed within 0.1 pH unit with that determined by the <sup>14</sup>C-DMO method.

Carboxy SNARF-1 is said to be more sensitive than either BCECF or ADB over the pH range 7.0-8.0<sup>1727</sup>; the dye is also better retained than ADB<sup>1728</sup>. Simultaneous detection of conjugate formation between cytotoxic and target cells during the cytotoxic process and determination of cytoplasmic [Ca<sup>2+</sup>] and pH are possible if one cell type is labeled with Fluo-3, and the other with SNARF-1; events positive for both dyes are identified as conjugates<sup>1729</sup>.

In studies of rat basophil leukemia cells, Lee et al<sup>1730</sup> observed that external bicarbonate was necessary for pH regula-

tion in these cells; it is thus advisable to have bicarbonate in your buffer when doing pH measurements.

Carboxy SNARF-1 and other dyes, e.g., BCECF and indo-1, are typically loaded into cells as acetoxymethyl (AM) esters; the hydrolysis of these esters results in a net acidification, and probe-induced perturbations, problematic in [Ca<sup>2+</sup>] studies with quin-2 (p. 403), may also need to be considered in critical analyses of pH<sup>1731</sup>.

Measurement of pH in intracellular compartments is feasible if you can localize the pH indicator to those compartments. McNamara et al<sup>12847</sup> coated small polystyrene beads with phospholipids covalently labeled with fluorescein (pH-sensitive) and tetramethylrhodamine (pH-insensitive). The lipobeads are ingested by macrophages and directed to lysosomes; fluorescence measurements by flow or image cytometry can, respectively, provide values of average lysosomal pH or of the pH in an individual lysosome. Levitz et al<sup>12838</sup> covalently labeled the fungus *Cryptococcus neoformans* with fluorescein and 2',7'-difluorofluorescein (Oregon Green), which, respectively, have pK<sub>s</sub> of 6.4 and 4.7, respectively, allowing sensitive pH detection over a broad range. They used the labeled fungi to study phagosomal pH.

Chitarra et al<sup>12839</sup> used ratiometric flow cytometric measurements of CFSE fluorescence to estimate internal pH in the bacterium *Clavibacter michiganensis*, taking the ability of cells to maintain a high pH in media of lower pH as an indicator of viability. This is, in effect, a rather fancy way of doing a dye exclusion test. It should not come as a surprise that the rather broad distributions of CFSE fluorescence ratio did not completely distinguish viable and killed cell populations; as was mentioned on pp. 256 and 402, if you only have a few thousand molecules of dye to work with, you probably won't get enough photoelectrons to do a precise measurement. The method would almost certainly work better in a slow flow, scanning or imaging system; others have reported making reasonably precise measurements of bacterial pH with the latter<sup>2840-1</sup>.

### The Hat Trick: Multiparameter Approaches to Ion Flux Measurements in Cell Activation

It has been my experience that you can use good parameters in multiparameter measurements to help make sense of bad ones. When I started working with membrane potential and immunofluorescence, using only forward scatter measurements for gating, I always suspected that I was measuring garbage along with my cells. I feel much more comfortable when I gate on Hoechst dye fluorescence, because I'm sure there's really a cell there.

Until I got ratiometric pH measurements working, I had no way of improving my conception of what was going on in flow cytometric estimation of ΔΨ with cyanine dyes, [Ca<sup>2+</sup>] measurements with quin-2, etc. I thought I might be able to clarify things a little bit if I correlated signals from these probes with measurements of the amount of labeled ligand bound to the cell surface, but I couldn't work up

much enthusiasm about this because I'd be looking at haystack vs. haystack. When ratiometric pH and  $[Ca^{2+}]$  measurements became available, the picture changed considerably, and it became logical to reformulate some of the questions I originally tried to ask when there was finally some hope of answering them.

Since I wanted to look at stimulation of cells by ligands that react with cell surface receptors, I envisioned ways of getting some kind of dose-response curve, for which I would need a labeled ligand. If the ligand were bound covalently to a fluorescent bead, I could count the number of beads bound to a cell to determine the "dose" of ligand, and follow the time courses of  $[Ca^{2+}]$ , pH, and/or  $\Delta\Psi$  changes in cells with various numbers of beads to determine the "response."

I figured that if I had the right dyes and the right excitation beams, I would be able to get measurements of  $[Ca^{2+}]$ , pH, membrane potential, and ligand binding all at once, assuming that probe interactions wouldn't cause big problems. Since I and others<sup>872, 1718, 1729, 1737-9</sup> had done simultaneous measurements of multiple functional parameters, I thought (and think) the assumption was (and is) fairly safe. And, of course, I'd have at least one or two fluorescence channels available to gate out cell subpopulations

This is still about as fancy a flow cytometric experiment as I can conjure up; not surprisingly, it takes a fairly elaborate flow cytometer, with four beams. As it happens, all four beams (UV, violet, 488 nm, and red) can be derived from small, air-cooled lasers that plug into the wall. Nicer still, once we put the beast together, we can use it to do almost all of the other measurements that have been discussed in this chapter (I said all this in the previous edition, in 1994; in 2003, as you will find in Chapter 8, you can buy such an instrument).

I puckishly referred to the experiment described above as the hat trick, because it had three goals and might net me some valuable information about early events in cell activation if I could stick to it. However, it's on ice for now, and maybe for good. The reason is simple. A flow cytometer, no matter how fancy, is not very good at looking at individual cells over time, and it has become obvious that we need to do more of that in functional studies.

Wacholtz and Lipsky<sup>1736</sup> used single cell image analysis of changes in cytoplasmic  $[Ca^{2+}]$  after mitogen stimulation of individual human T cells to determine the relation between the  $[Ca^{2+}]$  signal and subsequent functional changes. Marked heterogeneity was observed in the magnitude of increase in  $[Ca^{2+}]$ , in the lag time of responses, and in the percentage of T cells that responded to anti-CD3 and to PHA. However, mitogenic stimuli that induced IL-2 production or DNA synthesis consistently generated increases in  $[Ca^{2+}]$  that were sustained for 1 to 2 hours; elevations as small as 50 to 100 nM above control were associated with evidence of activation. Functional activation of T cells by PHA and anti-CD3 is thus correlated with the induction of small, but sustained increases in  $[Ca^{2+}]$  that might or might not have been detectable by flow cytometry. Image cytometry worked fine.

And, these days, while you're doing the image cytometry, you can use the patch clamp technique and other modern electrophysiological methods to follow fast membrane potential changes and dissect the roles of the various calcium, chloride, and potassium channels in activation processes in lymphocytes and other cells<sup>2842, 69</sup>. However, people who do that seem to use cell sorters to pick out interesting cells to work on, so you might want to finish the book before you order the new equipment.

## NOsing Around for Nitric Oxide

Rao et al<sup>1617</sup> described a method for detection of the production of **Nitric Oxide** ("Just Say NO"), now recognized as a key intermediate in cellular signal transduction, by neutrophils, in which DCFH-DA fluorescence was measured in cells to which calmodulin inhibitors had been added. There are a number of probes for NO; Several authors<sup>2870-2</sup> have used 4,5-diaminofluorescein; Molecular Probes<sup>2332</sup> recommends DAF-FM (4-amino-5-methylamino-2',7'-difluorofluorescein because it is unaffected by pH above 5.5 and more sensitive than other probes. These probes are all loaded into cells as "diacetates," i.e., as acetyl esters, in the manner of FDA.

## Other Ions in the Fire

Amorino and Fox<sup>2872</sup> describe measurement of intracellular **sodium** ion concentration using **Sodium Green**. Balkay et al<sup>2874</sup> measured intracellular **potassium** ion, deriving the parameter from measurements of pH (using BCECF) made in the presence of **nigericin**, which keeps the ratio of potassium and hydrogen ions constant on both sides of the cell membrane. Pilas and Durack<sup>2875</sup> used **6-methoxy-N-(3-sulfofpropyl) quinolinium (SPQ)**, a UV-excited, blue-green fluorescent probe quenched by halides, to measure intracellular **chloride** ion concentration. All of the probes mentioned come from – guess where – Molecular Probes, and the *Handbook*<sup>2333</sup> has much more information on them.

## 7.14 REPORTER GENES

### Somebody Cloned My Gal: Enzymes as Reporter Genes

In this era of molecular biology, flow cytometric detection of enzyme activity has come into increasing use as a method for detecting and selecting cells expressing **reporter genes**. Reporter genes are genes that encode protein products that are relatively readily detectable; they are linked by standard recombinant DNA technology to a gene or genes of interest to an investigator, and the resulting construct is introduced into cells. Those cells in which the gene of interest is expressed can then be identified by the presence of the reporter gene product.

In the 1980's, genes encoding **surface antigens** not normally present on the cells of interest were used as reporter genes; expression of these genes was detected by immunofluorescence. This was unsatisfactory; what was gener-

ally observed were very broad distributions of relatively weak signals, and successful isolation of cells bearing the genes of real interest to investigators generally required multiple cycles of cell sorting, in which the brightest cells were sorted and clones, and the brightest progeny were resorted, etc.

In 1988, the Herzenberg lab<sup>1642</sup> reported the development of a new method, called **FACS-Gal**, in which the *lacZ* gene from *E. coli* was used as the reporter gene. This gene encodes the enzyme  **$\beta$ -D-galactosidase**, which is not normally present in many eukaryotic cell types. The activity of this enzyme can be detected by flow cytometry using the fluorogenic substrate **fluorescein di- $\beta$ -D-galactoside (FDG)**, available from Molecular Probes, which is hydrolyzed to fluorescein by the enzyme. Since a few molecules of enzyme can produce a lot of molecules of fluorescein, the FACS-Gal technique made it much simpler to detect and sort cells expressing the reporter gene; the stronger signals also made it possible to distinguish cells expressing different amounts of the reporter gene and, therefore, of the gene(s) of interest, and to sort these separately for further analyses.

The FACS-Gal assay as originally published, although demonstrably usable (e.g., reference 1643) had some problems; loading the cells with FDG was difficult, and there were interferences from rare autofluorescent cells and from endogenous enzyme activity. Finally, it was difficult to do long sorting experiments because the enzymatic reaction continued over time. In 1991, several improvements were described by Fiering et al<sup>1644</sup>. Optimal loading conditions were determined, two-color fluorescence was found to identify interfering autofluorescent cells, chloroquine was used to inhibit endogenous mammalian enzyme, and **phenylethyl- $\beta$ -D-thiogalactoside**, a competitive inhibitor, was added to stop the enzymatic reaction before sorting.

Jasin and Zalamea<sup>1645</sup> reported isolation of galactosidase-bearing sperm cells from transgenic mice using **5-dodecanoylamino fluorescein di- $\beta$ -D-galactopyranoside**, a substrate that is more lipophilic than FDG; it may also be possible to use other substrates, e.g., **resorufin galactoside**<sup>1646</sup>, which has been used for analyses of galactosidase activity in yeast.

Genes encoding enzymes other than  $\beta$ -D-galactosidase may be used as reporter genes; Puchalski et al<sup>1646</sup> transfected COS monkey kidney cells with a construct incorporating a recombinant **glutathione S-transferase (GST)** gene, which was demonstrable using **monochlorobimane**, using procedures that were discussed in the section on analysis of thiol groups and glutathione (p. 381). More recently, Lorincz et al<sup>2876</sup> developed a reporter system using *E. coli*  **$\beta$ -glucuronidase** as the enzyme and **fluorescein-di- $\beta$ -D-glucuronide (FDGlcu)** as the fluorogenic substrate. Because selective inhibitors are available for  $\beta$ -glucuronidase and  $\beta$ -galactosidase, it is possible to detect both enzymes in transfected cells.

Puchalski and Fahl<sup>1647</sup> compared gene transfer by electroporation, lipofection, and DEAE-dextran transfection for compatibility with cell-sorting, with the requirements that

the procedure used should generate morphologically homogeneous populations with at least a 5% colony-forming ability in which at least 10% of the cells expressed recombinant GST. Of the transfection techniques tested, only electroporation satisfied all requirements.

At this point, I'm supposed to say "But that's all ancient history..." because you can see GFP and its friends and relatives just a little bit down the page. I will, instead, point out that enzymes are still being used as reporter genes. One of the newer wrinkles was developed by Roger Tsien et al<sup>2877</sup>, and made available by his company, **Aurora Biosciences**, which is now merged with **PanVera**. The enzyme is a  **$\beta$ -lactamase**, produced by the ampicillin resistance gene of *E. coli*; it is not found in untransfected mammalian or avian cells. The fluorogenic substrate used to detect it is called **CCF2**; it is loaded into cells as the acetoxymethyl ester, **CCF2-AM**. CCF2 contains a coumarin donor and a fluorescein acceptor attached to a cephalosporin  $\beta$ -lactam ring. When the ring is intact, the coumarin and fluorescein moieties of the probe are close enough together for energy transfer to occur, and excitation (the excitation maximum is 409 nm) produces green (530 nm) fluorescence. When the ring is cleaved by  $\beta$ -lactamase, the distance between the coumarin and the fluorescein is increased sufficiently to greatly reduce the efficiency of energy transfer, and the probe emits blue (450 nm) fluorescence. The intensity of blue emission from the hydrolyzed probe is about twice the intensity of green emission from the intact probe. CCF2 was not of great interest to the flow community when it was only feasible to excite it with a violet krypton laser; it may be a lot more interesting now that relatively inexpensive 405 nm violet diode lasers are available. Cavois et al<sup>2878</sup> used the  $\beta$ -lactamase/CCF2 system to develop an assay for HIV-1 virion fusion with target cells.

### Green Fluorescent Protein (GFP) et al

In early 1994, Chalfie et al<sup>1648</sup> described the use of a gene encoding an intrinsically fluorescent protein from the bioluminescent jellyfish *Aequorea victoria* as a reporter gene. The native **green fluorescent protein (GFP)** absorbs maximally at 395 nm, but can be excited moderately effectively at 488 nm, where its absorption is about one-third maximum; the emission spectrum has a sharp peak at 510 nm with a shoulder at 540 nm. I included this information in the previous edition; at the time, GFP expression in prokaryotic (*E. coli*) and eukaryotic (*Caenorhabditis elegans*) cells had been shown to render those cells fluorescent. I opined that "GFP should work for cell sorting, provided the cells used don't exhibit a lot of autofluorescence." Boy, did it. As I noted on p. 48, what I described in 1994 as a "mild mannered reporter" turned into Supermolecule. The first book<sup>2376</sup> and one of the big review articles<sup>2377</sup> are distinctly dated (1998), and it's hard to keep up with the literature. I won't even try. I don't do much GFP work, so I'll just try to cover some points that I think are important and point you elsewhere for more details.

Most of the probes we use in flow cytometry are things you add to cells after the fact. DNA dyes work on any cell that contains DNA, provided you can get the dye in. True, you wouldn't want to waste highly specific reagents, such as fluorescent antibodies and nucleic acid probes, on cells that you didn't think were carrying any detectable target material, but, in principle, you could throw any probe at any cell that comes through the door. Reporter genes, and fluorescent proteins in particular, are different; they have to be in or on the cells before they come through the door.

The protocols for labeling cells with fluorescent protein reporter genes are molecular biology protocols, not cytometry protocols; if your focus is on cytometry, what you need to know are the excitation and emission spectral characteristics of the proteins you're looking for and how much of them you expect to find in the cells. Figure 7-9 (p. 296) includes the spectra of four fluorescent proteins, **ECFP** (cyan; excitation maximum 434 nm, emission maximum 477 nm), **EGFP** (green; excitation maximum 489 nm, emission maximum 508 nm), **EYFP** (yellow-green, excitation maximum 514 nm, emission maximum 527 nm), and **DsRed** (orange; excitation maximum 558 nm, emission maximum 583 nm). They are all available, or, more accurately, the constructs you need to get the appropriate genes into cells are available, from **Clontech**, a division of **BD Biosciences**. Hawley et al.<sup>2879</sup> recently described flow cytometric detection of all four at once using 458 nm excitation from an argon laser for ECFP, EGFP, and EYFP and 568 nm excitation from a krypton laser for DsRed.

All of these proteins have been engineered to give them more desirable fluorescence characteristics. ECFP, EGFP, and EYFP, produced by mutants of the *Aequorea* GFP gene<sup>2577</sup>, are well-developed, as GFP variants go, while dsRed<sup>2459</sup>, derived from a coral of the species *Discosoma*, is more of a work in progress. There are several variants, including dsRed Express<sup>2884</sup>, which matures more rapidly and apparently yields more fluorescence than the original.

The longest wavelength fluorescent protein available from Clontech is HcRed, from the reef coral *Heteractis crispa*<sup>2880</sup>; its excitation and emission maxima are at 588 and 618 nm. HcRed could be excited by a 532 nm YAG laser, but the 568 nm krypton line, 590 nm from a dye laser, or 594 nm from a He-Ne laser (assuming you could get a He-Ne laser with enough power) would be a better bet.

As exploration of the animal kingdom<sup>2881</sup> and protein engineering<sup>2377,2459,2882</sup> have produced new and improved better fluorescent proteins, investigators have worked out optimal

schemes to detect them by flow cytometry and put them to use<sup>2886,96</sup>. We can expect that to continue.

The brief review by Matz et al.<sup>2881</sup> on GFPs packs more information into 7 pages than just about any other paper I have ever read; I heartily recommend it. Among other things, I learned that members of the GFP family are unique among pigment proteins in that they act as enzymes and synthesize their fluorophores from amino acids in their own polypeptide chains. Other pigment proteins, such as the phycobiliproteins, make their chromophores or fluorophores from small molecules and usually require several enzymes to get the job done. Thus, it would be a much harder job to make a phycobiliprotein reporter than it is to make a GFP reporter. The self-contained palette of GFP proteins also makes it much easier to modify their spectra by site-directed mutagenesis than it would be to change the spectrum of another type of pigment protein.

With a little help from their friends, GFPs themselves have "evolved" far beyond the point of merely marking transfection; there are fluorescent protein variants that are sensitive to pH<sup>2897-9</sup>, calcium ion concentration (shades of aequorin!)<sup>2900-2</sup>, and membrane potential<sup>2903</sup>, and others that monitor cell surface receptor interactions<sup>2378</sup> and kinase activities<sup>2904</sup>. There is also a "timer" protein<sup>2905</sup> that gradually changes color from green to red. Of course, you do have to put genes into your cells to take advantage of all these benefits; I can't help you much there.

### Minority Report(er)?

With fluorescent proteins and enzymes around, why does anybody still want to bother using proteins expressed on cell surfaces as reporters? Well, if your system works well enough so that only the cells expressing the reporter gene carry the product on their surfaces, you can then use antibodies on magnetic beads or a column to separate your transfectants instead of, or in addition to, a cell sorter. Christine et al.<sup>2906</sup> describe a system for detecting recombinant switch activity in B cells based on expression of CD4 or a histocompatibility antigen normally not found on the cells.

Well, that does it for parameters and probes. If you decide to quit at this point and get into image analysis or confocal microscopy, you'll be using many of the same probes, detectors, electronics, computers, etc., so you haven't wasted too much time. If not, stick with me, and I'll tell you how to acquire a flow cytometer, and then go on to a survey of some of the applications of the technology.

# 8. BUYING FLOW CYTOMETERS

## 8.1 INTRODUCTION

Flow cytometry obviously cannot be done without flow cytometers, most of which are bought from manufacturers. Users' buying decisions are generally based on examination of manufacturers' literature, on demonstrations, and on information obtained from more experienced users. I get a lot of phone calls from people who want to know which instrument they ought to buy, and/or whether they ought to try building one. In this chapter, I will try to give you access to the information necessary to formulate rational answers to these questions.

Since the manufacturers will happily provide potential customers with literature containing photographs, diagrams, samples of data obtained from their instruments, and reasons why you should choose that particular system, I will not attempt to duplicate their copiously illustrated brochures. You may, therefore, want to arm yourself with promotional literature before you look at what I say about companies and apparatus; addresses and phone numbers of the manufacturers of flow cytometers and other cytometric apparatus appear in Chapter 11, "Sources of Supply," near the back of the book.

The origins of cytometry have been discussed in Chapters 1 and 3. Chapter 4 provides information on light sources, illumination and collection optics, detectors, and electronics that is equally relevant to static and flow cytometry, as well as information on fluidics and flow system design, augmenting introductory material in Chapter 1. Data analysis hardware and software are introduced in Chapter 1 and discussed in detail in Chapter 5, and Chapter 6 is devoted to sorting.

I have included information on all the commercial flow cytometers I know about in this chapter; a selection of other cytometric apparatus is discussed in Chapter 10.

## 8.2 HISTORY

Only a few companies make or have made cell sorters and/or optical flow cytometers intended for research and/or clinical use. By 1970, **Bio/Physics Systems**, which was founded by Lou Kamentsky, was selling its Cytograf and Cytofluorograf instruments, while **Phywe AG** marketed **Partec's** commercial version of the Dittrich/Göhde ICP apparatus. Shortly thereafter, **Technicon** brought out the Hemalog D, the first of a series of flow cytometric leukocyte differential counters. **Becton-Dickinson** introduced the FACS cell sorter, based on the instrument developed in Len Herzenberg's lab at Stanford, in 1974; within a year, **Coulter** entered the cell sorter market with its TPS-1, later replacing this apparatus with the EPICS series, development of which was begun by Mack Fulwyler and continued by Bob Auer. In 1976, following its acquisition by Johnson & Johnson, Bio/Physics Systems became **Ortho Diagnostics Systems**; Ortho acquired marketing rights to the ICP from Phywe in 1978, and added cell sorters to its Cytofluorograf line at about the same time.

In the 1980's, alternatives to products of the "Big Three" American manufacturers, B-D, Coulter, and Ortho, began to emerge. At the beginning of the decade, these three companies offered laser source flow cytometers with cell sorting capability; sorting was optional on Ortho's instruments. Ortho also offered the arc source ICP, which could not be equipped for sorting, and the laser source Spectrum III, a highly automated system, without sorting, aimed at clinical users. In pursuit of the same market, B-D introduced the FACS analyzer, a small but sensitive analytical apparatus employing an arc lamp source, and Coulter produced the EPICS C<sup>873</sup>, an ergonomically designed, computer-controlled "knobless" instrument that included sorting capability. During the 1980's, the arc source apparatus of

Lindmo and Steen<sup>100,1</sup> was commercialized as the MPV-Flow by **Leitz**; a refined version of this instrument, the Argus, was later produced by **Skatron**, and marketed in Europe by Ortho and in the U.S. by **Bruker**, which also introduced the Odam A1C 3000, a laser source sorting apparatus developed in France, which could make electronic volume measurements as well as optical measurements. A later version of the Lindmo/Steen instrument was made and sold by **Bio-Rad**; one is now being produced by **Apogee**, which also offers service for earlier versions.

An apparatus using arc lamp and/or laser sources, based on Eisert's designs<sup>168,616-9</sup>, was sold for a time by **Kratel**, which also marketed data analysis hardware and software developed by Kachel. A later version of this data analysis system, and Kachel's Fluvo II flow cytometer, which made fluorescence and electronic volume measurements, became available from **HEKA**. **Partec** offered another arc source instrument, designed by Göhde and incorporating optical and electronic measurements and a closed fluidic sorter. Finally, three Japanese companies, **JASCO**, **Omron**, and **Showa Denko**, produced laser source instruments; Omron's was distributed in Europe by Ortho, and was the predecessor of the Cytoron Absolute, Ortho's last entry in the market.

After 1985, both B-D and Coulter brought out non-sorting benchtop instruments (the B-D FACScan and Coulter EPICS Profile) using low-power, air-cooled argon laser sources, and oriented at least as much toward the clinical as toward the research market. The efficient optical designs used in these instruments provided sensitivity at least equal to that obtained from these manufacturers' larger systems. Ortho, which, interestingly enough, had offered similar instrument configurations for years, ceased production of flow cytometers and sold its service operations to B-D in mid-1987. It reentered the American market in 1992, selling the Cytoron Absolute, built in Japan by Omron, and gradually withdrew again by the end of the decade.

**Cytomation**, a company founded in 1988, produced a series of add-on upgrades to improve data processing and sorting performance of existing cell sorters until 1994, when it began selling the MoFlo modular high speed cell sorter developed at Lawrence Livermore National Laboratory by Ger van den Engh and his coworkers<sup>1130</sup>. It was common to refer to B-D, Coulter, and Ortho as the "Big Three" of flow cytometry in the 1980's, if the term is used today, it denotes the trio of **BD Biosciences**, **Beckman Coulter**, and **Cytomation**, now **DakoCytomation**. I suspect that Becton-Dickinson decided on the "BD Biosciences" name when Coulter briefly jumped ahead of it in alphabetical order, becoming Beckman Coulter after being acquired by Beckman in 1997, but I can't prove it. The Big Three are the big makers of high speed sorters, but no longer the only makers; Ger van den Engh's new company, **Cytopeia**, arrived on the scene in 2000, and is now producing a relatively compact high speed sorter, the Influx, which, as of mid-2002, was to be sold by DakoCytomation, which has had an ongoing working arrangement with Cytopeia. **Systemix**, which had

licensed the MoFlo technology from Livermore for clinical applications, decided not to pursue production of instruments.

I estimated in Chapter 1 that there were between 12,000 and 20,000 benchtop argon laser source flow cytometers in use worldwide, and fewer than 2,000 large systems with droplet sorting capability. It is therefore likely that several manufacturers have more instruments in the field than does Cytomation; **Luminex** and **Partec** come to mind. However, if we really want to get into a competition on eliminating fluid waste about this, perhaps we should do just that, and ask the manufacturers to supply us with the total volumes of sheath run through all their instruments per year. They don't know, and they probably wouldn't tell us if they did.

Six manufacturers returned detailed responses to a questionnaire I sent out in October 2001, asking for details about their instruments, and, as far as I am concerned, they are "The Big Six" for taking the time to do so. Their products are discussed in some detail in the sections of this chapter immediately following. Then comes a section that covers instruments from other manufacturers who did not return the questionnaire, but, in some cases, did send back some information. The rest was filled in from the manufacturers' web sites and literature, and/or from personal inspection. A separate section is devoted to clinical hematology instruments. Manufacturers are listed in alphabetical order within sections (with one exception, to be explained later).

I'll take the rap for the errors, but if some item of information about a particular instrument is of critical interest to you, check it out with the manufacturer. I tabulated the features of various instruments in the last edition of this book; I'm not going to do it this time around because there are too many instruments and too many features.

## 8.3 BD BIOSCIENCES

### Background

The large cell sorter products from B-D began life differing only slightly in construction from the apparatus built by Herzenberg et al at Stanford<sup>2,9,82,86</sup>; more changes have since been made in the electronics and data analysis systems than in the optics.

The original FACS instruments used pulse height analyzers for data analysis; the FACS IV replaced a hardwired analyzer with the one that incorporated a dedicated minicomputer, allowing multiparameter analysis and sorting and data storage on magnetic media. In the next successor line, the FACS 400 had a minimal data analysis system that only generated dot plots; regions of interest for sorting could be defined on the two-parameter live display. The FACS 420 used an 8-bit microprocessor-based data analysis system that was also sold with B-D's arc source FACS Analyzer, the company's first entry into the non-sorting benchtop analyzer market. The FACS 440 had the same minicomputer-based data analysis system used in the FACS IV. The minicomputer was buttoned up so tightly within the system that it

was literally impossible to take advantage of its computer capabilities; at least one user site installed a second computer to eliminate the drudgery of pushing all the buttons that had to be pushed to get the data analyzer to do anything useful.

Things were much improved when B-D elected to offer users a choice of micro- or minicomputer-based data analysis systems. The smaller CONSORT 30 and 32 systems were built around Hewlett-Packard Series 300 microcomputers using a 68000 series microprocessors running under a Pascal operating system. The larger CONSORT 40 incorporated a DEC MicroVAX minicomputer with a graphics terminal. A range of applications programs, and various combinations of floppy and hard disc storage, were offered for both computer systems, as was networking capability. In the mid-1990's, both the Consort 30 and Consort 40 series of data analysis systems were replaced by the FACStation series, which incorporated Apple Macintosh computers. The hardware and software have progressed from Motorola 680X0-based Macs to newer PowerPC-based current models.

BD Biosciences' current large Fluorescence Activated Cell Sorter (FACST<sup>TM</sup>) is the FACSVantage SE<sup>TM</sup>, which succeeded the FACStar, FACStar<sup>PLUS</sup>, and FACSVantage. The company also makes three smaller instruments, the FACSCalibur<sup>TM</sup> and BD<sup>TM</sup> LSR II analyzers and the FACSAria<sup>TM</sup> high-speed sorter. These benchtop systems require neither special wiring nor water-cooling; the LSR II and FACSAria feature FACSDiVa<sup>TM</sup> digital pulse processing, also available as an option on the FACSVantage SE<sup>TM</sup>.

Except for the FACSDiVa option, which has a 6-month warranty, all BD Biosciences' instruments and additional components, including lasers, have a one-year warranty. Any options purchased after purchase of a new instrument have a 3-month warranty. A 4 1/2 day Key Operator Course is provided for 2 operators with each instrument purchase; an additional course is provided with the purchase of the FACSDiVa Option.

### The BD FACSVantage SE<sup>TM</sup> Cell Sorter

Figure 8-1. The BD FACSVantage cell sorter.

### Light Sources and Illumination Optics:

The FACSVantage SE (Figure 8-1) can use as many as three laser beams to illuminate observation points separated in space. Available lasers include water- and air-cooled argon, krypton, or mixed-gas ion lasers, He-Cd, He-Ne, and 635 nm diode lasers. A dye laser may be added if another laser (water-cooled argon or frequency-doubled YAG) is available for optical pumping. Excitation optics are adjustable, allowing the user to steer the laser beam(s) and control the spacing between beams; an adjustable lens can be used to change the beam shape at the interrogation point.

### Flow System:

The FACSVantage SE is a stream-in-air system, with ceramic orifice nozzles ranging in diameter from 50 to 400  $\mu\text{m}$  available. Sheath and sample are pressure-driven; flow velocity is typically 10 m/s, varying with orifice size, and is adjustable by changing sheath pressure. Sample pressure is continuously adjustable from 2.0 PSI, for the 400  $\mu\text{m}$  orifice, to 60 PSI, when the high speed TurboSort option is used with a 70  $\mu\text{m}$  orifice. Fluid flows downward.

### Forward Scatter:

An adjustable horizontal blocker bar and adjustable iris diaphragms allow the lower limit of collection to be set between 1° and 4°, and the upper limit to be set as high as 10°. A photodiode detector is standard; a PMT is optional.

### Side Scatter and Fluorescence:

Signals are collected around a horizontal blocker bar by an N.A. 0.55 lens; an adjustable iris serves as a field stop. Detectors are Hamamatsu PMTs; three fluorescence detectors are standard, with additional detectors optional. BD Biosciences' Special Products Group can provide as many as twelve fluorescence detectors. Field stops are used in the optical system to limit the region of space from which light reaches the detectors; an image ( $\geq 40\times$ ) of each beam intersection point is formed in the plane of the corresponding field stop. When multiple illuminating laser beams are used, combinations of half mirrors and dichroics divert light from different observation points to different detectors. Filters and dichroics can be selected, and easily removed and changed, by the user.

### Signal Processing:

BD offers two markedly different systems for signal processing and data acquisition; each has its own hardware, software, and computer platform. The standard FACSVantage SE uses analog and hybrid electronics for pulse processing; the FACSDiVa Option provides digital pulse processing.

#### Analog Electronics (standard):

Any parameter measured at the first observation point can be selected as a trigger signal. Current to voltage conversion of detected light pulses is done by a 20,000 V/A transimpedance amplifier with baseline restoration; further analog signal amplification is available. Linear signals are converted to a logarithmic scale by analog log amps with 4 decades of dynamic range. Fluorescence compensation for spectral overlap is done in hardware. Pulse integrals are captured

by active integrators; peaks are captured by peak detectors. A pulse width measurement circuit that measures width at a constant fraction of pulse height provides information for doublet detection. The pulse peak, integral and width measurements from the analog electronics are digitized by 10-bit ADCs. The system allows a maximum acquisition rate greater than 30,000 events/s.

#### Digital Electronics (FACSDiVa Option):

Any signal measured at any observation point, or any Boolean combination of measured signals, can be used for triggering. Current-to-voltage conversion of detector signals is accomplished by transimpedance amplifiers with baseline restoration, but no additional analog amplification is available. Instead, all signal pulse trains are simultaneously sampled and digitized by 14-bit (16,384 channel) ADCs at 100 ns intervals (10 MHz conversion rate). An integral is obtained by taking the sum of at least 16 values collected during the pulse, providing a range of values running between 0 and 262,143 (18 bits). The maximum 14-bit value among these is taken to represent pulse peak height. Linear signals are converted to a logarithmic scale by digital processing, using an 18-bit look-up table. Both hardware and software fluorescence compensation can be implemented. The maximum data acquisition rate is 100,000 events/s, but may decrease with the number of signals being measured.

#### Sample Handling:

The standard sample tube used is 12 × 75 mm, with a minimum volume of 100 µl and a maximum of 4.5 mL. Temperature control for sample input and output is provided by circulating chilled or heated water through a water jacket surrounding the sample tube holder.

#### Sorting:

A piezoelectric transducer is used to generate droplets for sorting with the TurboSort Plus option; the MacroSorting option uses an electromagnetic transducer to provide the relatively high amplitudes and low frequencies needed for droplet generation when large orifices are used to sort correspondingly large particles. Sort rates vary depending on the nozzle size used, with larger nozzle sizes yielding slower sorting rates. Rates range from 35,000 to 2,000 events/s using the TurboSort Plus nozzles (50 to 100 µm diameter), and from 500 to 100 events/s using the MacroSorting nozzles (200 to 400 µm diameter). As many as four sort streams may be generated. Single cells can be sorted into multiwell plates; each cell's location can be stored in the list mode data file. Both analog and digital sort decision hardware are available.

#### Software:

##### For Use with Standard Analog Electronics:

CellQuest Pro software is provided for the analog electronics workstation, built around an Apple Macintosh computer with a G4 PowerPC processor. The FCS 2.0 data file format is used. The software allows protocol definition and batch analysis. As many as 8 parameters may be acquired; as many as 16 parameters, including parameters, such as ratios, derived from the acquired parameters, may be analyzed. Single parameter histograms may contain as many as 1,024

channels. The available 2-D display formats are dot, density, and contour plots. Rectangular, polygonal, elliptical, "Snap-to-Gate," and "Auto-polygon" regions can be defined, and Boolean combinations of regions can be used. Mean, median, peak channel (mode), SD, and CV are available for statistical analysis of data. Overlay of single parameter histograms may be used to compare histograms. There is provision for 3-D display of data, DNA histogram analysis (provided by third-party software), and export of data to graphics and spreadsheet programs.

##### For Use with FACSDiVa Option:

The FACSDiVa Option software is provided for the digital electronics workstation, built around a Hewlett-Packard X4000 (Intel/Windows) computer. Both FCS 3.0 and 2.0 file formats are supported. The software allows protocol definition and batch analysis. A maximum of 16 parameters can be acquired, with a total of 36 parameters for analysis; these include area and height for all 16 parameters acquired plus two ratio channels and a width and a time parameter. Linear to log transformation and fluorescence compensation are done in software. The maximum number of channels in a single parameter histogram is 262,141. Dot plots are the only available live 2-D displays. Rectangular, polygonal, elliptical, "Snap-to-Gate," and "Auto-polygon" regions can be defined, and Boolean combinations of regions can be used. Mean, median, SD, CV, minimum, and maximum are available for statistical analysis of data. DNA analysis is provided by third-party software and graphics and spreadsheet export are possible.

#### Other Details:

The Vantage SE (crate and frame) is approximately 100 cm wide × 182 cm long × 154 cm high, and weighs 286 kg. The DiVa option is 105 cm wide × 123 cm long × 94 cm high, and weighs 113.4 kg. Aerosol containment and bio-hazard controls include the application of a vacuum to the sort chamber to contain aerosols formed during sorting, and a drip containment system on the sample injection tube deals with drips from the sample introduction area. The instrument console operates on 110 VAC ± 10%, 50/60 Hz, 20 A, or 230VAC, 50Hz. Each laser has its own specific power requirements.

Daily instrument optimization is needed to guarantee optimal performance. Sensitivity is configuration dependent. Fluorescence channels have detected <200 Molecules of Equivalent Soluble Fluorochrome (MESF) using Spherotech Rainbow RCP-30-5A particles. When using Bangs Laboratories' Quantum particles labeled with fluorescein, it has been possible to discriminate particles bearing <1,000 fluorescein MESF. The CV of fluorescence from propidium iodide-stained chicken erythrocyte nuclei is 3% or less.

#### The BD FACSCalibur™ Analyzer

The FACSCalibur, successor to the FACScan and FACSsort, is a benchtop analyzer, with optional fluidic sorting. The primary excitation light source is a 488 nm air-cooled argon ion laser; a 635 nm diode laser is optional.

Forward and side scatter and three colors of fluorescence can be measured in the single 488 nm laser system, a fourth color is available with the 635 nm diode laser option. The cytometer and the computer system with which it is used take up about six running feet (less than two running meters) of bench space, as shown in Figure 8-2. The applications software includes numerous routines for automated setup, calibration, and data analysis.

Figure 8-2. The BD FACSCalibur benchtop cell sorter.

#### Light Sources and Illumination Optics:

The primary 488 nm laser beam is made elliptical by prisms and focused to a spot 20  $\mu\text{m}$  high  $\times$  60  $\mu\text{m}$  wide at the sample stream. The optics allow fine adjustments of the beam pathway. The optional 635 nm diode laser is mounted at right angles to the 488 nm laser; the 635 nm beam, which is already elliptical, bypasses the prisms, is reflected off a mirror, and passes through the same optics used to focus and steer the 488 nm beam. The 635 nm diode laser is focused upstream from the 488 nm laser; i.e., cells pass through the 635 nm beam first.

#### Flow System:

The quartz flow cuvette has inside dimensions approximately 180  $\times$  430  $\mu\text{m}$ . The sheath fluid is driven by pressure from a 4 liter pressurized tank; stream velocity through the flow cell is 6 m/s. Three fixed sample flow rates, 12, 35, and 60  $\mu\text{l}/\text{min}$ , are available. Because the cuvette is rectangular, the core stream is elliptical; its size depends on the sample flow rate and the sheath pressure, with the slowest sample flow rate yielding the smallest core cross-sectional area. Fluid flows upward in the flow cuvette.

#### Forward Scatter:

A fixed vertical blocker bar is used to block the laser beam, and forward scatter signals are collected over a fixed range from 0.7° to 10°. In the dual laser 4-color setup, a 488 nm bandpass filter with a 10 nm bandwidth is placed in front of the scatter detector to eliminate scattered red laser light.

#### Side Scatter and Fluorescence:

The collection optics of the FACSCalibur follow the design originally used in the FACScan, providing efficient enough light collection to permit the use of low power lasers without sacrificing measurement sensitivity. Side scatter and

fluorescence signals are collected using a custom-designed, long-working distance, N.A. 1.2 objective optically coupled to the flow chamber with a thixotropic gel. Magnification is approximately 13  $\times$ . Field stops (1 mm wide in fluorescence channels and 1.5 mm wide for side scatter) are placed in the image planes in front of the PMT detectors. Three fluorescence detectors are used with the standard 488 nm laser; an additional fluorescence detector may be installed with the optional 635 nm diode laser. The filters normally used in the standard instrument provide for measurement of green (515-545 nm; "FL1"), yellow (564-606 nm; "FL2"), and red (> 670 nm; "FL3") fluorescence, excited at 488 nm. A fourth channel, measuring red (653-669 nm; "FL4") fluorescence excited at 635 nm, is added when the red laser is used.

#### Signal Processing:

Any signal or the Boolean AND of two signals may be used for triggering. A 20,000 V/A transimpedance amplifier with baseline restoration is used for current to voltage conversion of detector signals; additional analog signal amplification is available. Linear signals are converted to log using 4-decade analog log amps. Fluorescence compensation for spectral overlap is done in hardware. Pulse integrals are captured by active integrators; peaks are captured by peak detectors. Pulse width at a constant fraction of pulse peak height is available for one fluorescence detector. Data are digitized by 10-bit ADCs. The data acquisition system can process more than 30,000 events/s.

#### Sample Handling:

The FACSCalibur uses the same tube size and minimum and maximum volumes as the FACSVantage. However, the FACSCalibur also has an automated option for 12  $\times$  75mm sample tube handling and 96 well microplates.

#### Sorting:

A closed system fluidic sorter is optional; the sort mechanism moves a collecting tube into the center of the flowing stream when a cell of interest passes by. The sort rate of 300 selected events/s is adequate for many tasks, and the closed system is advantageous for work with hazardous samples. However, since fluid is continuously collected by the sorting mechanism, it may be difficult to isolate rare cells, because they end up being highly diluted in the collection vessel. Although BD provides a concentrator module that continuously removes fluid from the sorted fraction using a filter that resides in a pressurized chamber, this filtration process has been shown to damage some types of live cells, and is considered most useful for sorting fixed cells or cells that do not need to remain viable after sorting.

#### Software:

CellQuest Pro software is provided on an Apple Macintosh G4 computer; the FCS 2.0 file format is used. A maximum of 6 parameters can be acquired, and 7 parameters, plus time, can be analyzed using CellQuest. The features of CellQuest software are described in the previous section on the FACSVantage.

**Other Details:**

The cytometer itself is 91.4 cm wide, 61.5 cm deep, and 67.3 cm high, and weighs approximately 109 kg. Aerosol containment and biohazard controls include closed fluidic sort paths and an automatic aspirator on sample inlet tubing. Power requirements are 120 VAC +/- 10%, 50/60 Hz, 20 A. Bangs Laboratories Quantum beads bearing <750 fluorescein MESF have been discriminated from unlabeled beads. The CV of propidium iodide-stained chicken erythrocyte nuclei is 3% or less.

**The BD™ LSR II Analyzer**

The BD LSR II is BD's newest benchtop analyzer, with as many as four fixed alignment laser sources and as many as fifteen fluorescence and two scatter channels. The older BD LSR was configurable with as many as three lasers and six fluorescence channels. The two systems use the same instrument enclosure (Figure 8-3); the LSR II replaces the LSR's analog signal processing with digital signal processing.

Figure 8-3. The BD LSR™ multi-beam benchtop analyzer.

**Light Sources and Illumination Optics:**

The LSR was available as a two or three laser source system that used a Coherent 488 nm, 20mW air-cooled argon ion laser, a Kimmon 325 nm, 8mW HeCd laser, and, optionally, a 633 nm, 17mW HeNe laser. The LSR II can use Coherent's "Sapphire" solid-state laser for 488 nm and Lightwave's mode-locked 355 nm YAG laser for UV; the Coherent VioFlame 405 nm, 25mW diode laser and a 638 nm diode laser are available as options.

**Flow System:**

The LSR and LSR II use the same flow cell and external fluidics setup as the FACSCalibur.

**Forward Scatter:**

The setup is apparently similar to that used in the FACSCalibur.

**Side Scatter and Fluorescence:**

The LSR and LSR II use a gel-coupled, N.A. 1.2 collection lens with a larger field of view than that of the lens used in the FACSCalibur. The LSR used field stops, mirrors, and dichroics similar to those in the FACSCalibur. In the LSR II, light from an image of each interrogation point is relayed through a multimode fiber optic, and signals from different spectral bands are separated by (highly) reflective dichroics placed in a polygonal pattern (Figure 8-4). Filters and lenses

placed between the dichroics and the detector PMTs, correspondingly placed in a polygonal array, further restrict detector bandwidth. The older layout shown in Figure 8-4 allows seven detectors to collect a signal from one excitation beam; the current configuration provides for eight detectors. The dichroics are specially designed to work at the acute angles of incidence (not the customary 45°) necessitated by the octagonal layout. Light loss is minimized because each signal is required to pass through only a single optical filter, i.e., that placed immediately ahead of the detector. The relay fiber optics do not preserve polarization, likely precluding using the optical arrangement for polarized fluorescence or scatter measurements. On the plus side, I note that the use of fiber optic relay elements could allow light collected by a second lens placed 180° from the existing lens to be routed to the same detector, potentially doubling signal intensity; however, BD apparently does not now plan to offer this option.

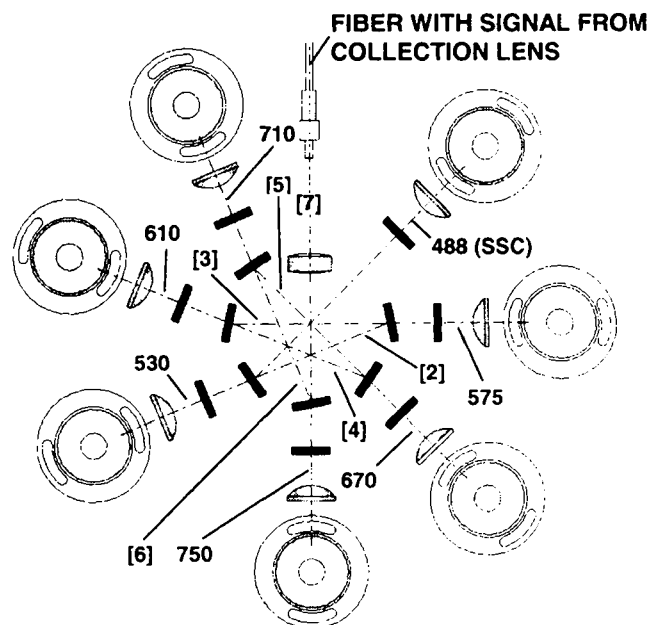

Figure 8-4. BD's "Octagon" collection optics. A number in square brackets associated with a path indicates the number of spectral bands traveling along that path; a number without brackets indicates the center wavelength (in nm; my guesses) of a single spectral band.

All fluorescence and side scatter detectors are Hamamatsu PMTs; all filters and dichroics can be changed as needed. Typical optical filter setups for the three laser source LSR II are: FL1 = 530 nm band pass (BP), FL2 = 575 nm BP, FL3 = 670 nm long pass (LP) or 682 nm BP, FL4 = 500 nm BP, FL5 = 380 nm LP, 400 nm BP, or 424 nm BP, FL6 = 610 nm BP or 660 nm BP.

**Signal Processing:**

While the LSR used essentially the same signal-processing scheme as the FACSCalibur, the LSR II uses the FACSDiVa digital data acquisition system described in the previous section on the BD FACS Vantage system.

**Sorting:**

Not available.

**Software**

The LSR II uses the FACSDiVa Option software (see the previous section on the BD FACS Vantage). The standard BD LSR used CellQuest software, provided on an Apple Macintosh G4 computer. Data from as many as 6 fluorescence and 2 scatter parameters could be acquired, and as many as 8 parameters, selected from peak height, pulse width, area, and ratio, could be analyzed. All other features of the LSR's CellQuest software were as described for the FACSVantage. Software fluorescence compensation for LSR and LSR II systems is provided for by the included FlowJo™ analysis software (Tree Star, Inc.); DNA histogram analysis is provided for by the included Modfit LT™ software (Verity Software House).

**Other Details:**

The Sensor module is approximately 193 cm wide, 87 cm deep, 127 cm high, and weighs 239 kg. Aerosol containment and biohazard controls include closed fluidic paths and an automatic aspirator on the sample inlet tubing. The BD LSR requires two dedicated 120 VAC +/- 10%, 50/60 Hz, 20 A power lines.

The estimated detection limit is 200 fluorescein MESF, when using the Spherotech Rainbow RCP-30-5A Beads; the fluorescence CV of propidium iodide or Hoechst 33342-stained chicken erythrocyte nuclei is 3% or less.

**The BD FACSAria™ Cell Sorter**

The FACSAria (Figure 8-5), introduced in December, 2002, is a multilaser high-speed sorter that departs substantially from the design of other current commercial products of this type; to start with, it is a benchtop system requiring less than 1 kW of electrical power from standard 110 V, 60 Hz or 220 V, 50 Hz lines.

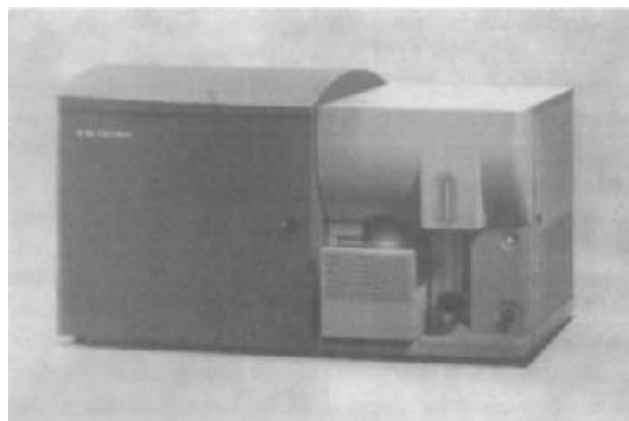

Figure 8-5. The BD FACSAria™ Cell Sorter

**Light Sources and Illumination Optics:**

The system uses two or three lasers; a 20 mW, 488 nm Coherent Sapphire solid state laser and a 17 mW, 633 nm He-Ne laser are standard, and a 20 mW, 407 nm violet di-

ode laser is optional. The 407 nm laser can be used to excite usable fluorescence signals from Hoechst dyes used to stain DNA in living cells. Fiber optics (single-mode for the TEM<sub>00</sub> sources) relay the illuminating laser beams to collimating lenses, from which they enter a series of four prisms that form elliptical spots 9 μm high × 65 μm wide, separated by 200 μm, on the sample stream inside a quartz cuvette. Optical alignment is fixed.

**Flow System:**

The quartz flow cuvette has a 160 × 250 μm rectangular cross section 15 mm in length. Both sheath and sample fluids are driven by pressure; sheath and cleaning fluid containers and a waste fluid tank are kept on an external cart with integral air pressure and vacuum supplies. Sheath fluid is transferred from the container on the cart into a reservoir inside the instrument, removing air bubbles and maintaining constant pressure independent of the fluid level in the external sheath container. The sample container accommodates a variety of sizes of sample tubes; once a tube is loaded, the container is sealed and pressurized, and the tube holder agitates the sample during the run to minimize settling of cells. Drive pressure can range from 2-75 PSI (14-517 kPa); typical stream velocity through the flow cell is 6 m/s. Because the cuvette is rectangular, the core stream is elliptical. Fluid flows downward; the stream exits the cuvette via a 70 μm or 100 μm nozzle.

**Forward Scatter:**

The setup is apparently similar to those used in the FACSCalibur and LSR II.

**Side Scatter and Fluorescence:**

Optical alignment is fixed; light is collected by a gel-coupled, N.A. 1.2 collection lens, similar if not identical to that used in the LSR II. Separate relay fiber optics transfer the signal from each beam to a polygonal array similar to that shown in Figure 8-4; an "octagon," more properly a nonagon, allows collection of as many as 8 signals (7 fluorescence signals plus side scatter) from the 488 nm beam intersections. As many as 3 signals (each) may be collected from the 633 nm beam and from the 407 nm beam. All detectors are Hamamatsu side-window PMTs; filters and dichroics may be changed as needed.

**Signal Processing and Software:**

The FACSAria uses the Windows-based FACSDiVa digital data acquisition system and software described in the section on the BD FACS Vantage cell sorter; a faster DSP chip is incorporated than was used in the original FACSDiVa, and additional software routines have been added to control sample handling and sorting.

**Sample Handling:**

The sample delivery system is, as mentioned, compatible with a variety of tube sizes; an arrangement for microplate sampling is likely to be made available in the future. The sampling tube is flushed inside and out with sheath fluid between samples to minimize carryover. There is also provision for filling the entire sample holder with ethanol for cleaning and disinfection.

**Sorting:**

Interchangeable 70  $\mu\text{m}$  or 100  $\mu\text{m}$  nozzle tips can be fitted to the cuvette with no adjustment required. Both two- and four-way sorting are possible; the system can process up to 60,000 compensated 8-parameter events/s and achieve a 100 kHz droplet generation rate at 75 PSI drive pressure. A camera monitors the position of the droplet breakoff point, and the transducer drive signal amplitude is controlled to maintain this position, keeping the droplet delay constant unless a clog or other substantial interruption of flow should occur. In these cases, fluid flow is shut off and the sample collection tubes are covered. During operation, both sample injection and sort collection chambers are closed; the sort chamber is sealed and operates under negative pressure. An additional Aerosol Management Option is available, which evacuates the sort collection chamber through a 0.01  $\mu\text{m}$  filter to trap aerosolized particles.

**Other Details:**

The benchtop portion of the FACSAria is 122 cm wide  $\times$  74 cm high  $\times$  71 cm deep and weighs 160 kg; space on the benchtop is also needed to accommodate the workstation keyboard, mouse, and LCD display. The fluidics cart, which can be placed on the floor, is 81 cm wide  $\times$  66 cm high  $\times$  66 cm deep and weighs 46 kg.

The estimated detection limit is  $<125$  fluorescein MESF. CVs of 1.5% and 3.5% respectively, have been observed from the major fluorescence peaks of propidium- and Hoechst dye-stained chicken erythrocyte nuclei.

It is claimed that people with little or no technical training in flow cytometry or sorting can be taught to operate the FACSAria in substantially less time than is required to train operators of other high-speed cell sorters. This certainly sounds plausible.

**The BD FACSCount**

The FACSCount is a small (smaller than the FACScan) benchtop instrument dedicated to performing counts of CD4- and CD8-positive T cells<sup>2472,3159</sup>. It uses a 543 nm green He-Ne laser source, and measures fluorescence in two emission regions from phycoerythrin and a tandem conjugate. Prepackaged reagents incorporating a known concentration of fluorescent beads are used to allow derivation of absolute counts. The system is designed for use in parts of the world where HIV infection is common and facilities and money to support flow cytometers and cytometry are scarce.

**8.4 BECKMAN COULTER, INC.****Background – and Signal-to-Background**

By the 1970's, Wallace Coulter had already built a highly successful company that sold hematology counters utilizing his impedance-based cell detection and volume measurement method. He recognized both the scientific and commercial potential of fluorescence flow cytometry and cell sorting early enough to get his company into the cell sorter business by the end of the decade.

The original EPICS instruments collected fluorescence and side scatter using a pair of high-N.A. aspheric lenses, the first of which, placed at a distance equal to its focal length from the observation point, formed a "collimated beam," and the second of which brought that beam to a new focus, with a relatively large diameter field stop in the focal plane limiting the region of space from which light could reach the detectors. This system collected more light from cells than did some imaging systems, but the signal-to-background ratio was lower because background fluorescence and Raman scatter were collected from a much larger volume. While older stream-in-air EPICS cytometers could detect as few molecules of fluorescein as their competitors, there was more of a problem with phycoerythrin sensitivity due to Raman emission from water; this would have been largely avoided by the use of image forming optics. The interim solution was to use a smaller diameter field stop.

Collecting a collimated beam instead of forming an image also made it more difficult to use multiple excitation beams; imaging systems could separate optical signals from the two beam intersection points, while the EPICS optics, which could not, made it necessary to collect electronic signals using a **gated amplifier**, which turned the detectors on only when cells were traversing the appropriate beam. This, however, did not eliminate steady state fluorescence background from dye in the core stream; this could, in theory, be a problem in such applications as measurements of fluorescein immunofluorescence in cells also stained for DNA with DAPI. Although measurements I made on a Cytomutt set up with "nonimaging" optics indicated that interference between DAPI and fluorescein was insignificant in practice, there was some concern about other dye interactions. However, in this era of eight-color measurements, Coulter, now Beckman Coulter, has made the issues moot by using imaging optics for fluorescence and side scatter collection in its current instrument line.

Forward-looking from the beginning, Coulter used microprocessors in the EPICS line. The original research instruments were equipped with the MDADS data acquisition and analysis system; the main processor was an 8086 with an 8087 floating point coprocessor, and an 8080 was also used. Data storage was on 8" floppy or cartridge discs.

Coulter was also the first of the manufacturers to make the move to personal computers for data analysis, with the EASY-88 computer system, which used IBM PC-compatible hardware, including 5 1/4" floppy and hard discs and a removable-cartridge high density disc system, a floating point processor, and a 640  $\times$  480, 4096-color graphics display. Instruments could be linked in an Ethernet-compatible network. The EASY-88 was said to be 2-3 times faster than a DEC PDP-11/23 minicomputer system.

Beckman Coulter's current analyzers and sorters are laser source flow cytometers with an orthogonal geometry. The EPICS<sup>®</sup> ALTRA<sup>™</sup> with HyPerSort<sup>™</sup> sorter (Figure 8-4) and Cytomics<sup>™</sup> FC 500 analyzer (Figure 8-5) are designed primarily for research laboratory use, while the EPICS<sup>®</sup> XL and

XL-MCL analyzers are aimed at both clinical and research laboratories. All of the instruments come with a one-year warranty on all parts including the laser, with longer warranties available; the standard service option is five days during business hours. A five-day training course or optional training in customer's lab is provided.

### The Beckman Coulter EPICS® ALTRA™ Cell Sorter

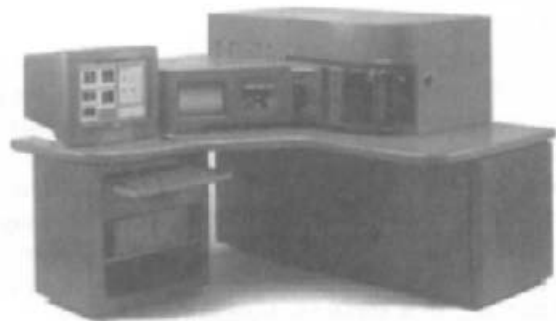

Figure 8-6. The Beckman Coulter EPICS® ALTRA™ sorter.

#### Light Sources:

All lasers on the ALTRA are optional and are customer-interchangeable on an industry standard optical table. A large variety of air-cooled and water-cooled lasers are available.

#### Illumination Optics:

The laser beam(s) are focused using crossed cylindrical lenses, and a variety of beam focusing lens assemblies are provided. The following focused beam spot sizes (height  $\times$  width for a 488 nm laser beam) are available: 16  $\times$  64, 16  $\times$  85, 16  $\times$  125, 6  $\times$  100, 8.5  $\times$  125, 16  $\times$  33, and 11  $\times$  125  $\mu\text{m}$ . Inter-beam distances are set in time, not space, as 7, 20, 40 or 60  $\mu\text{s}$  separation, meaning the beams are spaced not more than 100  $\mu\text{m}$  apart at the sample stream.

#### Flow System:

A variety of flow chambers are available. For analysis with a closed fluidic system, a 250  $\mu\text{m}$  square channel quartz cuvette with an integral N.A. 1.0 lens front element is used. For sorting, seven different jet-in-air nozzles, with orifice sizes ranging from 51-400  $\mu\text{m}$ , are available, as are quartz flow chambers with a variety of internal and jetting orifice dimensions. Flow rates or velocities are customer adjustable and vary with the flow cell and sheath pressure; sheath flow velocity can be adjusted from approximately 1 m/s to about 30 m/s. Sample flow rate, sample and sheath pressure are all continuously adjustable by the operator. The sample and sheath pressure are obtained from electronically regulated compressed air or nitrogen, provided by a compressor, a nitrogen tank, or the house air supply. Sample pressure is adjustable from 0 to 15 PSI for the standard system, and from 0 to 100 PSI with the optional high speed sorting (HSS) option. Standard sheath pressure is 12 PSI; the range

of adjustment is 1 to 100 PSI. Fluid flow is downward in sorting configurations.

#### Forward Scatter:

The forward scatter sensor, advertised as position-independent and using Fourier optics, incorporates two photodiodes as detectors; an optional PMT is available. The forward scatter collection lens N.A. varies depending on the collection half-angle used, which can be adjusted between 1.4° and 19°. For 2°, N.A. is 0.05; for 19°, N.A. is 0.40. The standard blocker bar is vertical; however, a variety of obscuration templates and different diameter field stops are available.

#### Side Scatter And Fluorescence:

The collection lens has an N.A. of 1.0. The first element is part of the flow cell, followed by an air gap; the other elements of the lens are contained in a brass cell, which is translatable to achieve best focus at the detectors. A 3  $\times$  magnified image of the interrogation point is formed inside the brass lens housing; a 500  $\mu\text{m}$  diameter field stop is mounted in the image plane. No obscuration bar is used with the quartz cuvette flow chambers; a 2.5 mm wide horizontal blocker bar is used across the front of the fluorescence collection lens when running in the jet-in-air configuration. Six fluorescence channels, using Hamamatsu R1923 PMTs as detectors, are standard. An R1923 is also used to detect orthogonal scatter signals. PMT voltages are set from DACs.

All fluorescence filters are customer-removable without any need for re-alignment. The filters supplied are optimized to detect FITC, PE, ECD (PE-Texas Red), PC5 (PE-CY5), PC7 (PE-CY7), APC, and APC-CY7. Each fluorescence PMT can be used to collect signals from 2 laser intersection points using the AUX Channel feature. This feature allows a single PMT to collect signals excited by different lasers from fluorochromes having similar fluorescence emission properties (e.g., PE-CY5 and APC).

#### Signal Processing:

Single or multiple trigger signal(s) can be selected and the operator can set a separate threshold level for each signal used. Transimpedance amplifiers are used for current-to-voltage conversion of the signal pulses. A proprietary (patent pending) baseline restoration circuit is used. Analog signals for all non-log parameters are amplified with step gains. DAC-based attenuators are used on the forward scatter detector amplifier to provide gain adjustment, as these detectors use photodiodes instead of PMTs. Analog log amplifiers are used, and fluorescence compensation is done by software incorporating a 6  $\times$  6 matrix inversion. Conventional peak detectors are used; integrators employ a switched capacitor circuit allowing the operator to select the time constant for either "conventional" or "high-speed" operation. The conventional mode allows the highest sensitivity to be obtained, using sheath pressure  $\leq$  15 PSI, with signal pulse widths 5-15  $\mu\text{s}$ . For high-speed operation, at pressures up to 100 PSI, pulse width is less than 5  $\mu\text{s}$ , and often 1-2  $\mu\text{s}$ . Pulse peak and integral values are digitized to 10 bits.

The maximum acquisition rate depends on the number of parameters being collected, pulse width, and operator-selectable settings. The ALTRA processes the data pulses significantly faster than its predecessor, the Elite; conversion time is 1.1  $\mu$ s per parameter and the ADC skips over unused parameters. Acquisition of one-parameter data with synchronous pulses could proceed at a rate of 130,000 events/s; real world numbers are, obviously, lower, but are compatible with acquisition of multiparameter data from 20,000 cells/s and sorting with a 100 kHz droplet generation frequency.

#### Sample Handling:

Tubes 12  $\times$  75mm, 12  $\times$  76mm and 17  $\times$  100mm can be used, with no minimum sample volume. At present, there is no automated option for sampling from tubes or multiwell plates. An available module for sample delivery and sorting utilizes a re-circulating water bath providing temperature control from 4-40  $^{\circ}$ C.

#### Sorting:

The ALTRA generates droplets at approximately 25 kHz using the 100  $\mu$ m tip and 90-100 KHz using the high-speed sorting 76  $\mu$ m tip; it provides for two sort streams. A low abort rate and high purity are achieved when a cell is put into every 5th drop, corresponding to maximum analysis and sort rates of 5,000 events/s using the 100  $\mu$ m nozzle and 20,000 events/s using the 76  $\mu$ m tip. Users can sort faster based on the required specifications for purity and yield of their applications. Sorting of single cells into a large variety of multiwell plates (6, 12, 24, 48, 60 and 96 wells) or onto standard microscope slides is possible using the optional **AutoClone™** sorting module.

#### Software:

The ALTRA uses EXPO32, a Microsoft Windows based data acquisition and analysis software package utilizing the FCS 2.0 file format. Users can utilize "canned" protocols supplied with the software or can create unique protocols and combine them into a Worklist. Protocol definition includes parameters, plot definitions, gates, regions, and cytometer settings as well as disposition of the data, e.g., print-out and archiving.

A maximum of eight parameters can be acquired from the instrument; derived parameters such as time, ratio, and time-of-flight (T-O-F) can also be computed and processed. The "PRISM" parameter allows identification and quantification of cell populations based on "positivity" or "negativity" for as many as six markers, in which case there are 64 possible categories of cells. Gated data acquisition is possible. The software does logarithmic/linear transformations and solves the matrix equation for fluorescence compensation. The maximum numbers of channels in single-parameter histogram and 2-parameter displays are, respectively, 1024 and 1024  $\times$  1024. The display scale can be converted to a MESF or ABC (Antibodies Bound per Cell) scale after running appropriate bead controls. The following 2-D display formats are supported; dot, density, contour, and PRISM plots. Rectangular and polygonal regions can be created and combined using Boolean logic, with a maximum of 32 gates

and 256 regions. Mean, median, mode, SD, CV, percentiles (%gated, %total) and counts of cells/ $\mu$ l can all be obtained. Comparison of data can be achieved by use of overlay plots of 1-D and 2-D data, as well as the calculation of Overton and K-S statistics. Isometric display of 1-D data and 3-D surface and tomogram plots are also available.

DNA analysis is provided by the 3rd party software package MultiCycle for Windows. Plots and histograms can be exported as PDF files, or into Microsoft Windows applications. Data can be exported in a text format or directly into Microsoft Excel.

#### Other Details:

The cytometer is approximately 132 cm high  $\times$  178 cm wide  $\times$  198 cm deep (including the tabletop) and weighs 500 kg, excluding water-cooled lasers. Aerosol and biohazard containment are provided by negative pressure in the sorting compartment that draws aerosols into the compartment, down a tubing vent and onto a filter that can be changed daily. The cytometer, workstation and air-cooled lasers require two 100/115 VAC, 20 A (16 A continuous) or two 220/240 VAC, 10 A 50/60 Hz dedicated power lines.

An on board, adjustable-rate, flashing LED provides a light source for testing detectors independent of the laser and flow chamber alignment; it can also be used to calibrate the gains of various signal pathways. Standard beads and bead sets must be run and recorded regularly to ensure proper alignment and calibration of the instrument.

In most configurations, <1,000 MESF of fluorescein and phycoerythrin can be detected; when the system is optimized for sensitivity, approximately 300 molecules of fluorescein and around 500 molecules of phycoerythrin can be detected. Fluorescence CVs of approximately 2% are achieved when measuring propidium iodide-stained peripheral blood lymphocytes. Using an optional PMT combined with a blocker optimized for low angle detection of forward scatter, particles as small as 0.14  $\mu$ m diameter can be resolved above background.

### The Beckman Coulter Cytomics™ FC 500 Analyzer

The FC 500 (Figure 8-7) is Beckman Coulter's newest benchtop analyzer, providing 5-color analysis from either single or dual laser excitation sources, with digital fluorescence compensation and log display using 20-bit linear list mode data.

#### Light Source:

The standard excitation source in the FC 500 is an air-cooled 20mW, 488 nm argon-ion laser; a 20mW, 633 nm He-Ne laser can be added. In the dual laser configuration, the laser beams are collinear, with no provision for multiple interrogation points.

#### Illumination Optics:

The beam(s) is/are focused by crossed cylindrical lenses to an elliptical spot 10  $\mu$ m high  $\times$  80  $\mu$ m wide at the sample.

#### Flow System:

A 150  $\times$  450  $\mu$ m rectangular channel quartz cuvette is used; sheath and sample flow upward. There are three user-

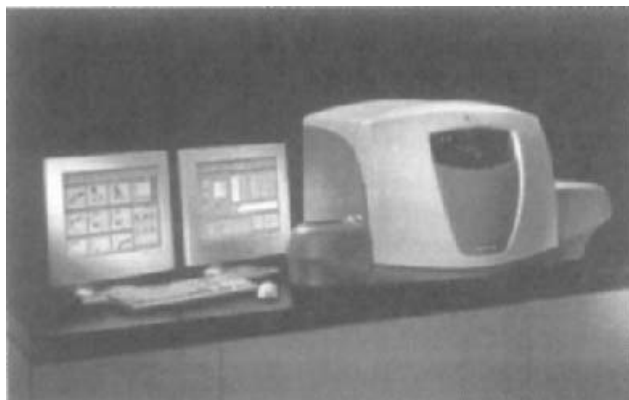

Figure 8-7. The Beckman Coulter Cytomics FC 500 analyzer.

selected sample flow rates, yielding data rates, on a sample of  $10^6$  cells/mL, of approximately 200, 600, or 1200 events/s. The sheath flow rate is fixed.

#### Forward Scatter:

As with the ALTRA, two solid-state detectors are used to collect forward scatter signals over a range of half-angles from  $2^\circ$  to  $16^\circ$ ; the blocker bar has a "Maltese Cross" shape. An adjustable iris can be used to limit the half angle of collection to  $8^\circ$ . The forward scatter collection lens N.A. varies with the collection angle, ranging from 0.05 to 0.37.

#### Side Scatter and Fluorescence:

The front element of a N.A. 1.2 lens is built into the flow cell; a blocker bar is unnecessary. Additional, focusable lens elements form a  $3 \times$  magnified image; a  $500 \mu\text{m}$  field stop is placed in the image plane. A photodiode is used to detect orthogonal scatter. Five fluorescence channels are standard; the detectors are Hamamatsu HC-120-32 PMT modules with enhanced red sensitivity. All optical filters are interchangeable by the user without the need for optical realignment. Bandpass filters and dichroics optimized for detection of fluorescein, phycoerythrin, PE-Texas red, PE-Cy5 or APC, and PE-Cy7 are provided with the instrument. All fluorescence filters are mounted on a removable single optical block, positioned on precision-machined dowel pins.

#### Signal Processing:

A single selectable trigger channel is used to acquire data, and the current pulses from the PMTs are converted to voltage pulses by a transimpedance amplifier utilizing a proprietary baseline restoration method. Analog circuits provide peak and integral values of the voltage pulses; these are digitized to 20 bits and stored, allowing the software to do log conversions and log scale displays and a full matrix inversion solution for fluorescence compensation, either in near real-time or after data have been stored in files.

#### Sample handling:

Sample input uses  $12 \times 75$  mm tubes; sample volume typically is 0.5 mL, with a minimum of 0.25 mL and a maximum 3 mL. A 32 tube Multi Carousel Loader (MCL) with a presample bar code reader provides automated sample handling. An barcode reader wand is optional. Blood from

closed Vacutainer tubes (B-D) or their equivalents can be automatically prepared for immunophenotyping using the optional Prep Plus II, followed by the optional T/Q Prep, which lyses and fixes the samples. If the samples need to be washed, the carousel can be placed into the optional Cell-Prep module, which aspirates each sample's cells into a hollow-fiber filter with a pore size adequate to retain the cells, but which allows hemoglobin and unbound reagents to escape. The carousel is then placed into the FC 500 for analysis. An optional module will allow aspiration from 96-well plates. The FC 500 has a maximum acquisition rate of 3,300 events/s, but the actual throughput rate depends on variables such as the flow rate, cell concentration, and the number of parameters acquired.

#### Sorting:

Not available on the FC 500.

#### Software:

The FC 500 uses RXP Software, a Windows 2000-based acquisition and analysis package utilizing the FCS 3.0 file format. The software allows for user-defined protocols; these can be combined to automatically process 32 tubes in a carousel. The RXP Software incorporates most analysis capabilities of the EXPO 32 software and adds additional features. As many as 16 parameters, including derived parameters such as ratios, time, and PRISM, can be acquired; as many as 24 parameters can be analyzed. Logarithmic display and fluorescence compensation are done in software and the 20-bit linear data can be saved in both compensated and uncompensated forms. Single parameter histograms have 1024-channel resolution and two parameter displays can have resolution ranging from  $64 \times 64$  to  $512 \times 512$ . As many as 256 regions, of all types, can be created with as many as 32 regions available as gating regions; two to eight regions can be combined using Boolean logic for gating. Autogating, with user selectable levels, using elliptical and contour regions is available. All statistics are user definable on any histogram. Absolute cell counts using FlowCount™ fluorospheres are available. Display plots can be exported into Microsoft applications or converted to PDF files; data can also be exported directly into MS Excel or in text format. MultiCycle for Windows is provided for DNA analysis.

#### Other Details:

The current version of the FC 500 is approximately 61 cm high  $\times$  112 cm wide  $\times$  74 cm deep and weighs 85 kg. The power supply module is approximately 48 cm high  $\times$  41 cm wide  $\times$  51 cm deep and weighs 55 kg. The instrument and computer together require four dedicated 120V/20A or 240V/15A power lines. It is anticipated that a 20 mW, 635 nm diode laser may be substituted for the 23 mW, 633 nm He-Ne laser, and possible that a solid-state 488 nm source will be offered as well; this will allow the instrument to be housed in an enclosure only 90 cm wide.

To optimize instrument settings, the user can run the Auto Set-Up Wizard, which automatically adjusts PMT voltages, gains and color compensation settings while the appropriate bead sets and stabilized stained control cells are

run on the instrument. Analyzing Spherotech™ Rainbow Calibration particles, the FC 500 can detect <600 MESF in the fluorescein channel and <300 MESF in the PE channel. Running Linear Flow Beads from Molecular Probes less than 600 MESF can be detected by the APC channel. Forward scatter signals from 0.5  $\mu\text{M}$  diameter particles can routinely be resolved, and it is usually possible to resolve 0.3  $\mu\text{M}$  diameter particles from background noise. All fluorescence channels except the 755 nm (PE-Cy7) channel have half-peak CVs of 1-1.5% when detecting the fluorescence from beads, with some beads yielding CVs of less than 1%. Fluorescence from beads detected by the PE-Cy7 channel has half-peak CVs of approximately 2%.

### The EPICS® XL and XL-MCL Analyzers

The Beckman Coulter XL and XL-MCL (Figure 8-8) are non-sorting benchtop flow cytometers, designed for routine clinical laboratory applications as well as research use; they can measure as many as four fluorochromes excited by a single air-cooled laser. The XL-MCL includes a 32-tube multicarousel loader for automated sample handling.

Figure 8-8. The Beckman Coulter EPICS® XL-MCL analyzer.

#### Light Source:

The excitation light source is a JDS Uniphase 488 nm, 15 mW air-cooled argon ion laser.

#### Illumination Optics:

The laser beam is focused to an elliptical spot 10  $\mu\text{m}$  high by 80  $\mu\text{m}$  wide using crossed cylindrical lenses.

#### Flow System:

The flow system employs a 250  $\mu\text{m}$  square channel quartz cuvette with upwards sheath and sample flow and an integral N.A. 1.0 lens front element. As with the FC 500, there are three user-selected sample flow rates and a fixed sheath flow rate.

#### Forward Scatter:

The XL uses the same forward scatter collection lens, diode detectors in the Fourier plane and cross-shaped blocker bar setup as the FC 500, but without the adjustable iris; a neutral density filter is available to reduce forward scatter signal intensity by a factor of 10 for samples containing large particles.

#### Side Scatter And Fluorescence:

In combination with the front element built onto the flow cell, a multielement focusable lens forms a 3  $\times$  magnified image; a 500  $\mu\text{m}$  field stop is placed in the image plane. Like the FC 500, the XL uses a photodiode detector for orthogonal scatter. Three fluorescence channels are standard with an optional fourth channel; Hamamatsu R 1923 PMTs are used as fluorescence detectors. The standard four-color setup uses 525, 575, 620, and 675 nm bandpass filters and 488, 550, 600, and 645 nm dichroic long pass filters; a 488 nm blocking filter is also supplied. All optical filters are replaceable without need for realignment.

#### Signal Processing:

A single trigger channel is selectable. The XL uses the same combination of analog electronics and high-resolution digitization of the data pulses as the FC 500. Unlike the FC 500, the XL normally saves only 10-bit list mode data, although the 20-bit data are used internally for logarithmic conversion and fluorescence compensation. Linear, log and peak values of the pulse may be obtained from each fluorescence channel.

#### Sample Handling:

The XL uses the same size tubes and volumes as previously described with the FC 500. Samples can be prepared automatically with the XL-MCL using the optional Prep Plus II, T-Q Prep, and CellPrep stations as previously described with the FC 500, where the carousel is then placed into the XL-MCL for automated analysis. Throughput rates of greater than 100 tubes per hour can be achieved when acquiring 2,500 lymphocytes from a normal Q-Prep sample. The XL has the same maximum acquisition rate of 3,300 events/s as the FC 500.

#### Sorting:

Not available.

#### Software:

Two software packages are available, XL SYSTEM II software, version 3.0, and EXPO32 ADC software. Both are designed to accept industry standard barcodes when using the XL-MCL bar code reader and/or the optional wand, allowing for automated specimen identification. XL SYSTEM II software operates in a DOS environment under Windows 98SE and utilizes the FCS 2.0 file format. Batch processing and analysis of samples is possible. A maximum of 12 parameters, including time, ratio, and PRISM, can be processed, and gated acquisition is possible using as many as 8 regions from a total of 24 available. A variety of region types are available, and Boolean combination of regions is possible. A single parameter histogram has a maximum of 1024 channels, and a two-parameter display has a maximum of 256  $\times$  256 channels' resolution. A variety of two-parameter display formats are available and overlays of both one and two-parameter data are possible. The software provides for fluorescence compensation using direct visual adjustment. Three-dimensional data display is not available. A large variety of statistics is available, and absolute cell counts can be calculated with the inclusion of appropriate beads in

the sample. The software and available optional packages are designed to automate cell analysis and enumeration and report generation, all relevant for a clinical setting. Screen images can be captured in PCX format and ASCII file EPT format files can be generated. The software supports the industry standard SQL/ODBC database allowing for bidirectional connectivity to third-party software programs.

EXPO32 ADC software has the same features as the EXPO 32 software previously described with the ALTRA cell sorter, but includes Advanced Digital Compensation (ADC) for automated fluorescence compensation with up to four colors. A maximum of 16 parameters, including time, ratio, and PRISM can be processed. The software provides administrator tools that allow the operator to set user access levels, automate data archiving, and monitor usage for billing and accountability.

#### Other Details:

The XL cytometer is approximately 51 cm high × 61 cm wide × 57 cm deep and weighs 64 kg. The XL-MCL is approximately 25 cm wider and weighs 85 kg. The instrument requires space for ventilation: 31 cm from the back, 20 cm from the top, and 31 cm from each side. The Power Supply Module can be placed on the floor, is 48 cm high × 45.5 cm wide × 51 cm deep, weighs 55 kg, and requires 13 cm from the back for ventilation. The XL needs two dedicated 120V/20A or 240V/10A power lines; the XL-MCL needs an additional line.

Instrument settings, including compensation, can be set automatically using the software and running the appropriate bead sets and stabilized stained control cells. The user can change optical filters to optimize for fluorochromes other than FITC, PE, ECD, and PE-Cy5, and an optional PE-Cy7 optical kit is available.

The XL/XL-MCL can detect fewer than 1,000 MESF of FITC and PE on Bangs Laboratories' Quantum microbeads. The forward scatter channel can resolve 0.5 μm diameter plastic spheres from background noise. Precision is similar to that obtained using the FC 500.

## 8.5 DAKOCYTOMATION

### Background

Cytomation got its start by manufacturing and distributing the CICERO system, an add-on to existing flow cytometers which provided improved, faster sort control and data analysis<sup>1181-2</sup>. The first versions of CICERO incorporated a DEC PDP-11 minicomputer system; later versions progressed through VAX minis, and the last, much smaller, less expensive versions, which worked even better, incorporated Pentium-based PC's running MS-DOS.

The original MoFlo high-speed cell sorter was designed and built by Ger van den Engh and his colleagues<sup>1180</sup>, then at Lawrence Livermore Laboratory. It incorporated a parsimonious but flexible, bench-mounted optical design, allowing illumination of up to three observation points in a stream in air, and collection of forward and right angle scatter and

fluorescence in as many as six wavelength regions. MoFlo, while preserving high-speed sorting capability (100,000 events/s and analysis), was considerably simpler in design than the original high-speed sorter<sup>667</sup> built at Livermore, and incorporated a sophisticated parallel-processing data analysis and sort control system run from a NeXT workstation.

I have great respect for Ger van den Engh's flow cytometer design, possibly because he borrowed and improved on a couple of features of my "Cytomutts." I also was impressed by Cytomation's computer interface when Brian Hall demonstrated it on the Cytomutt in my lab almost ten years ago. It had 16-bit data analysis, although the dynamic range of its front end electronics was not sufficient to allow it to do digital linear-to-logarithmic transformation with a dynamic range greater than three decades.

In the last decade, Cytomation has taken its own approaches to high-speed, high dynamic range data acquisition and analysis, melding the mechanical, optical, and analog portions of the front end electronics of the MoFlo instrument with its own sort control and data analysis system and software, initially running under MS-DOS and now under Windows NT, 2000, and XP. Modular design allowed for everything from tabletop analyzers to console sorters to be included in the MoFlo line, the most recent addition being the CyAn, a modular benchtop analyzer.

DakoCytomation resulted from the recent marriage of Cytomation, a company dedicated to production of high-speed research apparatus, and DAKO, an antibody manufacturer with a heavy clinical orientation. The happy couple could produce some interesting offspring.

### The MoFlo® Cell Sorter

The MoFlo (see Figure 1-24, p. 58) is a modular, custom configured cell sorter built on an industry standard optical bench.

#### Light Source(s):

1-3 lasers; the system is user-configurable with any commercially available or prototype laser, emitting any wavelength(s) from ultraviolet to infrared, preferably in TEM<sub>00</sub>.

#### Illumination Optics:

Separate cylindrical and spherical beam-shaping optics are used with each laser, forming as many as three spatially separated interrogation points, typically spaced 50-100 μm apart.

#### Flow System:

The jet-in-air CytoNozzle™ can be used with interchangeable ceramic tips providing 50, 70, 80, 90, 100, 120, 150, 200, or 400 μm orifice diameters. Sample (core) flow rates can be as high as 1.5 μL/s, with core diameters up to 8.5 μm; fluid flows downward at velocities up to 30 m/s. Sample and sheath pressure can be as high as 100 PSI.

#### Forward Scatter:

A horizontal obscuration bar is used; sizes ranging from 0.5-5.0 mm are available. Light at angles up to 10° is collected by a N.A. 0.15 lens. The detector can be a 25 mm

Advanced Photonics high-speed photodiode or an H957 Hamamatsu PMT module. Fluorescence collection from the forward direction is available as an option.

#### Side Scatter and Fluorescence:

A long working distance (13 mm), 0.55 N.A. microscope objective forms a 50 × magnified image of the interrogation point; a horizontal obscuration bar (available range 0.5-3.5 mm) is normally used. As many as 14 detectors may be fitted; the standard detectors are Hamamatsu H957 modules incorporating 1 1/8" side-window PMTs, available in a range of red sensitivities, but other detectors, including photodiodes, are available on request. An assembly of three stacked field stops, one for each beam intersection point, is placed in the image plane; from this point, lenses, mirrors, and dichroics are used to separate signals in different spectral bands and route them to the detectors, each of which is equipped with an additional filter(s) to define its response characteristics.

#### Signal Processing:

As many as four trigger channels can be selected; the Boolean OR as well as the Boolean AND combination can be used for triggering. A high gain-bandwidth transimpedance amplifier converts PMT output current signals (typically 0-100 μA) to the 0-10 V range. The preamplifier circuit also includes baseline restoration and output buffers. Hybrid digital/analog log amplifiers provide 80 dB (4-decade) dynamic range on each channel; deviations from ideal response across the range are later corrected by digital processing. The analog electronics, including switched-capacitor integrators and peak detectors, can operate on pulses less than 1 μs in duration; peak and integral are computed and digitized to 16 bits' precision within 5.4 μs. Fluorescence compensation for multi-color overlap of as many as 8 colors is implemented by a 1.6 giga-instruction/s DSP chip, performing matrix inversion on digitized data after any necessary correction for nonideal log amp response.

#### Sample Handling:

MoFlo options allow for automated sample delivery from 0.6-50 mL tubes, with temperature control for input and output. The MoSkeeto™ AutoSampler provides for delivery from 96-well plates.

#### Sorting:

Droplet formation rates up to 200 kHz and as many as four sort streams are available. The CyCLONE® option permits single-cell sorting into 96/384/1536-well plates and user-definable slide formats with data available on each sorted particle.

#### Software:

The Windows NT-based Summit™ Data Acquisition and Analysis Software is also available for offline analysis. It reads and writes all FCS formats, and includes capabilities for gated acquisition, postacquisition fluorescence compensation, and manipulation of "unlimited" numbers of parameters, including real-time computed parameters, and of rectangular, polygonal, and/or elliptical regions. Single-parameter histograms may contain as many as 4,096 chan-

nels; dual-parameter resolution can be as high as 1,024 × 1,024. The software also has full statistical capabilities, "publication-quality" graphics and spreadsheet/database export capability.

#### Other Details:

Footprint, dimensions, and power requirements of MoFlo systems vary over a wide range depending on the number and type of lasers installed.

The CytoShield™ product line includes: a Class I Biosafety Cabinet featuring formaldehyde decontamination, negative pressure over the complete work area, remote controls, clog detection, and redundant HEPA filters; an Aerosol Evacuation System, which provides negative pressure to the sort chamber, extracting aerosols to ULPA filters; and a Sort Integrity System, with positive pressure to the sort chamber using ULPA-filtered air.

Sensitivity has been measured at <200 MESF using DAKO 6-peak Fluorosphere Calibration Beads; the fluorescence CV from DAPI-stained trout erythrocytes is <2%. Particles as small as 0.2 μm can be detected using the side scatter signal for triggering.

DakoCytomation provides comprehensive support through a Technical Support Call Center, Regional Field Service Engineers, CytoLink™ Real-time Diagnostics and Solutions, and the MoFlo® Users Group, with full warranties and a wide range of service contracts available. A week-long training course is available on site or at DakoCytomation.

## The CyAn™ Flow Cytometer

#### Light Source:

The CyAn (Figure 8-9) uses 1-3 fixed beams, typically deriving low-noise 351 nm, 50 mW and 488 nm, 150 mW beams, both TEM<sub>00</sub>, from a Coherent Enterprise closed system water-cooled argon laser, and a 635 nm, 12.5 mW beam from a diode laser. A 20 mW Coherent Sapphire solid state laser may be substituted as a 488 nm source, and a 405 nm, 25 mW violet diode laser is also available.

#### Illumination Optics:

Beam-shaping optics include cylindrical and spherical elements to provide illumination over as much as the entire 250 μm width of the flow chamber. Three spatially separated interrogation points are typically spaced 200-400 μm apart.

#### Flow System:

Observation points are inside a UV-grade fused silica cuvette with a 250 μm square internal cross-section; fluid flow is upward. Sample flow rates may be as high as 1.5 μL/s, with core diameters up to 12.5 μm. Sample flow velocity may be as high as 12 m/s, at the maximum 10 PSI sheath pressure.

#### Forward Scatter:

Observation in a cuvette allows a vertical, rather than a horizontal, obscuration bar (0.5-5.0 mm widths available) to be used in the forward scatter channel. The maximum angle of light collection is 10°. A 0.15 N.A. collection lens is used; the detector may be a photodiode or a PMT.

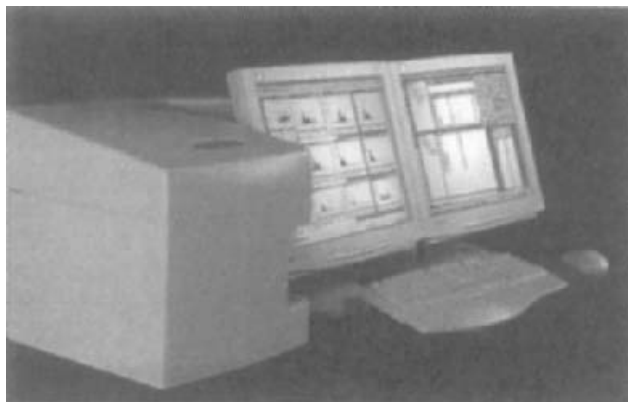

Figure 8-9. The CyAn benchtop flow cytometer.

#### Side Scatter and Fluorescence:

An aspheric lens, typically with 0.55-0.68 N.A., forms an image of the interrogation points, with a typical magnification of 12.5 ×; field stops similar to those used in the MoFlo are placed in the image plane. As many as 9 detectors may be mounted; these are Hamamatsu HC120 modules incorporating 1/2" side-window PMTs, with various red sensitivities available. Other detectors are available on request.

#### Signal Processing:

The CyAn uses essentially the same signal processing hardware and software as the MoFlo.

#### Sample Handling:

Manual loading from 5 mL tubes; automated, temperature-controlled delivery from tubes and multiwell plates should be available by the time this appears in print.

#### Sorting:

Not available.

#### Software:

Essentially the same as used with the MoFlo.

#### Other Details:

When it is equipped with the Enterprise laser the dimensions of the cytometer bench are 36 cm high × 116 cm wide × 57 cm deep. When all solid-state lasers (Coherent Sapphire 488 nm, violet and red diodes) are used, the bench is 36 cm high × 33 cm wide × 49 cm deep. The Enterprise laser requires 208-240V, 60 A, 3-phase power as well as the 110/220 V, 10/20 A, single phase power needed for the rest of the instrument. Various service, support, and training plans are available. Sensitivity has been measured at <200 MESF using DAKO 6-peak Fluorosphere calibration beads; the fluorescence CV from propidium iodide-stained chicken erythrocyte nuclei is <3%.

## 8.6 CYTOPEIA

You should, by now, have noticed that DakoCytometry and Cytopeia do not appear in the promised alphabetical order; I have two good reasons. The first is that DakoCytometry was Cytopeia until quite recently; the

second is that it was easier and more informative to discuss DakoCytometry first.

Ger van den Engh, who recently founded Cytopeia, shares my belief in Einstein's maxim that everything should be as simple as possible, but no simpler. However, while I tend to eliminate parts from my cytometers to save money, Ger's emphasis is on making his cytometers and sorters as efficient and reliable as possible. I have no doubt that he would be using diamond flow chambers if he thought they offered a performance advantage.

The MoFlo represented Ger's rethinking of the original Livermore high-speed sorter design in the late 1980's. A decade later, a good deal more had been learned about high speed sorting, and there had been considerable advances in computers, and some in electro-optics, as well. Since leaving Livermore for the University of Washington, Ger had built a series of sorters that incorporated new hardware, software, and knowledge as they became available, and he eventually got dragged into the business.

Cytopeia custom modifies instruments and prepares sorters for as many as three interrogation points, accommodating as many as four lasers, in which case two beams must be collinear. Fittings are provided to attach lasers selected by the customer to the optical bench. The first few instruments placed in the field have been designed to sort human cells for therapeutic use; the fluidics are placed in a clean room, with most of the bulky hardware and electronics behind a wall. However, the basic "InFlux" sorter design is modular, and in its simplest implementation, it provides an elegant, minimalist benchtop system. DakoCytometry will be selling one version of this instrument, with Summit software, under a preexisting cooperative agreement with Cytopeia.

### The InFlux Cell Sorter

#### Light Sources:

User-selectable. The DakoCytometry version will probably use Coherent's Sapphire solid-state 488 nm laser.

#### Flow System:

The InFlux (Figure 8-10) is a stream-in-air system with sample event rates ranging from 0 to 100,000 particles/s, nozzle diameters ranging from 50-200 μm, and flow velocities from 5-25m/s. Sheath drive pressure can vary from 10-100 PSI; sample is driven at a 0-5 PSI pressure differential with respect to sheath. Fluid flows downward.

#### Forward Scatter:

Collected over angles from 1.5 to 10° using a horizontal blocker bar. The collection lens has an N.A. of 0.5 with 20 × or 50 × magnification; a 1 mm diameter field stop is used. The detector is a PMT.

#### Side Scatter and Fluorescence:

The collection lens (N.A. 0.5, 20 × or 50 ×) forms an image of the interrogation points; light from each intersection point passes through an 800 μm field stop. A 1.5 mm horizontal blocker bar is used. As many as 28 fluorescence channels can be implemented; standard detectors are Hamamatsu 957-12 or 957-06 PMT modules, but any

Figure 8-10 Cytopeia's InFlux cell sorter platform.

PMT specified by the customer can be supplied. Spectral separation is accomplished by mirrors, filters, and dichroics. Fluorescence channels can be used for DC measurements; the system may be configured to measure laser output, temperature, sheath pressure, etc. Options include a monochromator for spectral measurements and magic angle collection optics<sup>24,39</sup> for precise polarization measurements.

#### Signal Processing:

The InFlux always uses parameter 1 as a trigger channel. Current-to-voltage conversion is done by transimpedance amplifiers; further signal amplification and logarithmic conversion are done by analog circuits, and both analog and digital baseline restoration can be implemented. Peak detectors and both switched-capacitor and pulse shaping integrators are available on all channels. The maximum data acquisition rate is 200 kHz, using as many as 28 parallel 16-bit ADCs.

#### Sample Handling:

Tube input: Tubes of a wide variety of sizes fit into the temperature-controlled sample holder. An automated sampler is not yet available.

#### Sorting:

Droplet sorting drive rates in the InFlux range from 25 kHz with the 200  $\mu\text{m}$  orifice to 125 kHz with the 50  $\mu\text{m}$  orifice. There can be as many as 6 sort streams. Indexed sorting into multiwell collection vessels, with all data stored for each sorted event, is available.

#### Software:

Cytopeia's InFlux software is Windows NT-based, using FCS file formats. The package is intended primarily for sort control and has limited analysis capabilities. Gated acquisition is possible with bitmaps for 12 parameters, and a maximum of 32 parameters. There is provision for 1024-channel single-parameter histograms and  $256 \times 256$  dot plots. Free-form gating regions can be defined for any two parameters in each of 12 bitmap spaces; AND and OR combinations are possible. A live 3-D display can be rotated

during data acquisition. The software also has statistical capabilities, including facilities for comparison of one- and two-parameter data. InFlux sorters sold by DakoCytomation will also be supplied with Cytomation's Summit software.

#### Other Details:

The instrument dimensions are determined by the lasers used; the sort module itself has a  $61 \times 61$  cm footprint. Dual biohazard containment is standard; a laminar flow unit is available. There is a one-year warranty on the sorter itself; laser warranties depend on the laser manufacturer(s). One week of training is provided with instrument. The sensitivity is sufficient for measurements of chromosomes and bacteria; fluorescence CV for chromosomes is 1% or better.

Inquiries about all versions of the InFlux should be referred to Cytopeia rather than to DakoCytomation.

## 8.7 OPTOFLOW AS

### Background

The Norwegian company Optoflow AS, a subsidiary of BioDETECT, manufactures the MICROCYTE<sup>®</sup> family of flow cytometers. The version designed for field use (see Figure 1-25, p. 58) is probably the smallest instrument currently available; there are also a benchtop version and one intended specifically for water analysis. While the instruments only measure fluorescence in one spectral region ( $>650$  nm), housings can be ordered in either red, green, blue, purple, or one of three shades of gray. These pioneering "designer cytometers" are available in the U.S. through BioDETECT's Texas subsidiary.

### The MICROCYTE<sup>®</sup> Flow Cytometer

#### Light Source:

635 nm, 5 mW diode laser.

#### Illumination Optics:

Polarizing optics are used to maximize scatter sensitivity and minimize interference of stray laser light with the fluorescence signal. The optics are built into a solid metal block.

#### Flow System:

The observation point is in a cuvette with a 250  $\mu\text{m}$  square cross section. Both core and sheath are driven by pumps; the sample flow rate is fixed at 0.5  $\mu\text{l/s}$ , facilitating calculation of particle numbers per unit volume.

#### Scatter and Fluorescence:

Two parameters are measured, with avalanche photodiodes (APDs) used as detectors for both. Scattered light is collected over a range of angles between  $10^\circ$  and  $30^\circ$ , intermediate between the ranges used for forward and side scatter in most other instruments. Fluorescence is collected at wavelengths above 650 nm (the detector response extends to 900 nm); sensitivity is reported as 1,000 MESF Cy5.

#### Signal Processing:

Either signal or both (in AND or OR combination) can be used for triggering. Preamplifiers incorporate current-to-voltage conversion and baseline restoration; analog log amplifiers are used. Data are converted to 8 bits' precision.

**Sample Handling:**

Tubes in a range of sizes, containing 0.1-1.0 mL of sample, may be used. Typical runs use fixed analysis times of 2, 20, or 200 s to analyze 1 to 100  $\mu\text{L}$  of sample; at a sample concentration of  $10^7$  cells/mL, the data acquisition rate is 5,000 events/s.

**Software:**

The lab and field versions of the instrument have the capacity to generate  $256 \times 256$  dot plots without an external computer. All versions can also be interfaced to a Windows-based PC; software provides for gated acquisition and two rectangular gating regions. Data can be stored in a proprietary format or as FCS 3.0 files, depending on the software used. Graphs can be saved as bitmaps and data exported to Microsoft Excel.

**Other Details:**

The field version of the MICROCYTE<sup>®</sup> is 33.3 cm wide  $\times$  33 cm high  $\times$  16 cm deep and weighs 12 kg; it can be operated from a 12 VDC source, drawing 2 A.

**8.8 PARTEC GMBH****Background**

Founded in the late 1960's, Partec has been producing fluorescence flow cytometers longer than any other company. In the original arc source Impulscytometer (ICP), marketed by Phywe AG and, later, by Ortho, cells flowed along the axis of illumination and light collection instead of perpendicular to it, and it was thought that this contributed to the extremely high fluorescence measurement precision achieved using this instrument. However, measurement precision of Partec's newer designs, sold under the Partec name since the 1980's, in which cells flow perpendicular to the illumination axis, has remained excellent, judging by published histograms of DNA content in cells stained with DAPI. Two spectacular examples appear in Figure 7-11 (p. 311).

Partec now offers instruments with arc lamp and/or laser sources, with optional fluidic sorting and electronic cell volume measurement. The new, modular CyFlow line (Figure 8-11) includes simple, single-laser, single-parameter instruments that can be run on batteries in resource-poor environments as well as multisource systems with digital processing, capable of measuring as many as 14 fluorescence parameters.

**The CyFlow<sup>®</sup> and CyFlow<sup>®</sup> ML Flow Cytometers****Light Source:**

The following sources are available: 100 watt long life Hg arc lamp (100 W), violet (nominal 407 nm) diode laser, blue (488 nm) solid state laser (20 or 200 mW), green (532 nm) Nd-YAG laser (up to 100 mW), or red (635 nm) diode laser (15 or 25mW, temperature stabilized). The CyFlow (Figure 8-11) uses a single source; the CyFlow-ML may be supplied with as many as 3 lasers plus the arc lamp.

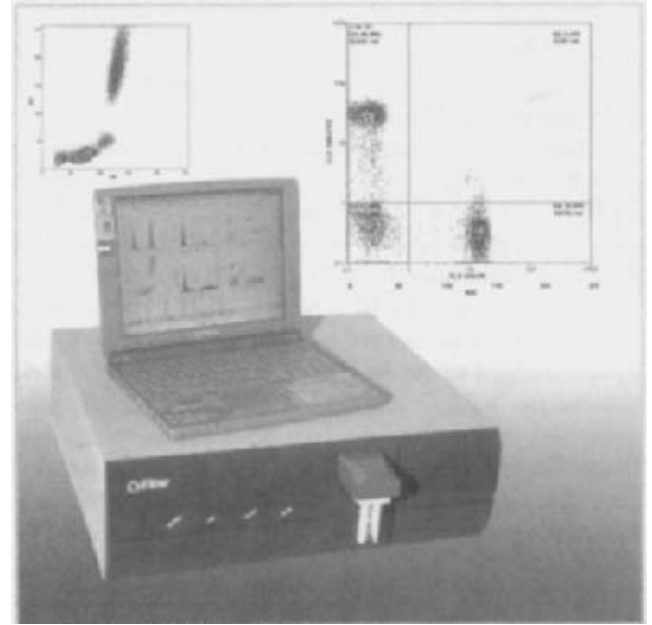

Figure 8-11. Partec's CyFlow flow cytometer.

**Illumination Optics:**

Köhler epiillumination optics through the microscope objective used for fluorescence light collection are used with the Mercury HBO arc lamp. Laser beams are normally focused with crossed cylindrical lenses, a separate set for each laser, to elliptical spots  $10 \mu\text{m}$  high  $\times$   $100 \mu\text{m}$  wide; other beam geometries are optional. A maximum of 3 interrogation points are spaced  $30 \mu\text{m}$  apart.

**Flow System:**

Cells are analyzed in sheath flow in a synthetic quartz flow cell with a  $250 \mu\text{m}$  square internal cross section. Sample flow rate is continuously adjustable by software between 0 and 3 mL/min. Flow velocity is typically 1 m/s, and is adjustable between 0 and 2 m/s. Typical core diameter is  $5 \mu\text{m}$ ; the adjustment range is  $5\text{-}50 \mu\text{m}$ . Core (sample) is driven by a computer controlled air syringe pump; continuous steady flow is possible. The sheath is driven by air pressure, typically 200 mbar (2.9 PSI), generated by a pump; pressure is software adjustable from 50-800 mbar, providing flow velocities between 25 cm/s and 4 m/s. Sample flow rate can be measured using an optical encoder on the software calibrated syringe pump or by a patented method that measures the time taken for a sample meniscus to traverse the known distance between two sensing electrodes in an input tube of known diameter. An electronic particle volume sizing measurement is available as an option.

**Forward Scatter:**

Forward scatter signals are collected by a long working distance lens; a vertical blocker bar and an iris, respectively, limit lower and upper collection half-angles. The CyFlow typically collects light scattered at angles between  $2^\circ$  and  $10^\circ$  from the axis of the illuminating beam. The CyFlow-ML can be equipped with two "forward scatter" channels, the first collecting at angles between  $2^\circ$  and  $6^\circ$  and the second at

angles between 6° and 14°. Angular ranges can be further restricted by substituting a wider blocker bar and/or a narrower iris. The standard detector is a PMT module.

#### Side Scatter And Fluorescence:

Objectives on opposite sides of the flow chamber are used to collect side scatter and fluorescence signals in the CyFlow®-ML. Partec has designed its own line of infinity-corrected Suprasil (quartz) microscope objectives with high UV light transmission. Both 20 ×, N.A. 0.65 and 40 ×, N.A. 0.8 dry objectives and a 40 ×, N.A. 1.25 glycerin immersion or gel-coupled objective are available, and may fairly readily be interchanged in the cytometers. Images are formed of the observation points, and, after passage through user-replaceable rectangular field stops 0.5-2 mm in width, light is recollimated before passing through or being reflected from dichroics or filters used for spectral separation. Standard detectors are Hamamatsu modules incorporating 1/2" side-window PMTs; a range of red sensitivities is available. The CyFlow is available with as many as 3 fluorescence channels and a side scatter channel; The CyFlow-ML can be fitted with 13 or 14 fluorescence channels and 2 or 1 side scatter channels. Filter sets for DAPI/Hoechst, fluorescein, propidium, PE, PE-CY5, APC, and a variety of other fluorochromes are available.

#### Signal Processing:

Trigger channel(s) are selectable; both upper and lower thresholds may be set, and both AND and OR combinations of signals used for triggering. Current-to-voltage conversion is accomplished by transimpedance amplifiers built into the PMT modules. Analog electronics provide baseline restoration and signal amplification with software-settable gains up to 1,000. The CyFlow utilizes analog log amplifiers selectable to produce linear, 3-decade log, or 4-decade log output; analog peak detectors, integrators, and pulse width measurement circuits process signals from each channel within 2 μs of the return of pulses to baseline, and output signals are digitized to 16 bits' precision. Electronics for all Partec flow cytometers are modular, with easily exchangeable boards in standard Euro-form sizes. Each channel is equipped with a card containing a high-speed, high-precision peak detector, integrator, and pulse width measurement circuit, with much of the circuitry digitally adjustable under the control of a custom designed application-specific integrated circuit (ASIC). Peak, integral, and pulse width are digitized by fast (1 μs) 16-bit ADCs, and transformation between log and linear scale data is accomplished by FloMax® software. The maximum data acquisition rate is > 10,000 cells/s.

#### Sample Handling:

The instrument accepts sample volumes from 0.5-2.2 mL in 2.5 mL Partec standard tubes. A mini-tube inset is available for sample volumes <0.5 mL.

#### Sorting:

Like many of the Partec cytometers, the CyFlow line can optionally incorporate a closed-system fluidic sorter, which diverts cells from the main stream into a sorting channel.

Only minimal amounts of fluid emerge from the channel when cells are not being sorted. The sorter can be built with a channel diameter large enough to permit sorting of much larger particles (e.g., pancreatic islets) than can be sorted in droplet sorters, albeit at substantially lower rates (300 objects/s). Sort decisions are made in <10 μs based on any logical combination of free form gating regions; sort dead time is <50 μs. Sort delay is set by examining an image of the sorting system taken with an included CCD camera. The sorting module is compatible with acquisition rates greater than 10,000 events/s, and can sort up to 1,000 events/s.

#### Software:

Partec's FloMax® software runs under Windows, and incorporates capabilities for instrument control, single- and multiparameter data acquisition, and analysis. A desktop PC or a notebook computer with a >1.8 GHz CPU, CD-RW drive, and Ethernet connection is normally supplied by Partec. Data from more than 10,000,000 cells can be recorded in a single FCS 2.0 acquisition file. There are extensive capabilities for protocol definition, sample identification using barcodes, and operation of a sample autoloader; runtime features include automated cluster analysis and full matrix fluorescence compensation, and absolute cell counts may be generated. Batch processing of files according to predefined templates is possible, and automated multi-tube panel reports can be generated in Word or Excel formats. Acquired parameters can include pulse height, area, and width for as many as 16 channels; an additional 16 derived parameters, including ratios and event number or time, can be processed as well. Extensive logical gating capabilities are provided; as many as 32 regions can be defined, with rectangular, polygonal, elliptical, or free form boundaries. The maximum number of channels in a single-parameter histogram is 65,536; a subregion may be displayed and/or printed out with full resolution. Two-dimensional distributions can be as small as 32 × 32 or as large as 1024 × 1024; displays available include dot and density plots, and a zoom function permits enlarged display of subregions. Histogram overlays and 3-D displays are also available. There are extensive statistical capabilities, including mathematical models for DNA histogram analysis and curve fitting. Data and graphics may be exported in a variety of formats; the software can also generate high resolution PostScript files.

#### Other Details:

The CyFlow measures 43 cm × 37 cm × 16 cm and weighs 8 kg; the CyFlow-ML measures 50 cm × 50 cm × 32 cm and weighs 15-20 kg depending on the choice of light sources. The CyFlow may be operated from a 12 V or 24 V battery; both instruments are operable from a single 100-230 V, 50-60 Hz AC power line.

#### The PAS, PAS II, and PAS III Flow Cytometers

The Partec PAS series flow cytometers (Figure 8-12) were the first commercial flow cytometers to combine arc lamp and laser sources. Like the CyFlow line, the line includes simpler and more complicated instruments built from

Figure 8-12. The Partec PAS cytometer.

a basic kit of modules. PAS instruments are larger than CyFlow instruments, and can accept larger lasers (e.g., air-cooled argon ion lasers).

**Light Source:**

Standard: 488 nm air-cooled argon ion laser (20-50 mW), mercury arc lamp (100 W), and 635 nm red diode laser (25 mW); Optional: 532 nm green Nd:YAG laser, violet diode laser, blue (490 nm) solid-state laser.

**Illumination Optics:**

Köhler epiillumination optics are used with the arc lamp; the illuminated area is  $50\ \mu\text{m} \times 100\ \mu\text{m}$ . Laser beams are focused to elliptical spots  $10\ \mu\text{m}$  high  $\times$   $100\ \mu\text{m}$  wide by crossed cylindrical lenses; other beam geometries are optional. The PAS can be fitted with as many as 3 light sources, with at most of 2 interrogation points separated by  $50\ \mu\text{m}$ ; The PAS III can use as many as 4 light sources, with at most 3 interrogation points separated by  $30\ \mu\text{m}$ .

**Flow System:**

Essentially the same as in the CyFlow cytometers.

**Forward Scatter:**

Essentially the same as in the CyFlow cytometers, except that the range of collection angles is  $2^\circ$ - $12^\circ$ .

**Orthogonal Scatter And Fluorescence:**

Essentially the same as in the CyFlow cytometers.

**Signal Processing:**

Either analog or digital processing; essentially the same as in the CyFlow cytometers.

**Sample Handling:**

Essentially the same as in the CyFlow cytometers; however, the PAS series can be fitted the ROBBY<sup>®</sup> Sample Automat and AutoLoader, a sample preparation and staining station which holds 36 sample tubes per carousel. Samples are prepared according to customized software defined protocols using Windows-based Partec Robby Prep software. The ROBBY can dispense antibodies, fluorochromes, lysing and fixation reagents out of a pool of 16 different chemicals, with adjustable sample incubation and mixing times. The ROBBY is also available as a stand-alone apparatus.

**Sorting:**

Essentially the same as in the CyFlow cytometers.

**Software :**

FloMax<sup>®</sup> software, as described in the section on the CyFlow instruments, is also available for the PAS line. Partec DPAC software, a simple single parameter analysis package running under Windows, is also available.

**Other Details:**

Dimensions of the PAS are  $77\ \text{cm} \times 50\ \text{cm} \times 55\ \text{cm}$ ; the weight is 35 kg. Dimensions of the PAS III are  $140\ \text{cm} \times 50\ \text{cm} \times 55\ \text{cm}$ ; the weight is 35-100 kg, dependent on which laser(s) is/are installed. The PAS series instruments operate on 110-240 V, 50/60 Hz AC current.

Warranty provisions: 12 months on all parts except filters, mirrors, other quartz or glass parts, disposables and cuvettes.

Service options: 1-3 year service contracts available.

Calibration materials: DNA Control UV for UV excitation or DNA Control PI for use with green or blue excitation are preparations of trout erythrocytes, used for precise alignment and target channel adjustments. Fluorescent beads and CountCheck beads are used for daily quality checks.

On-site training is provided with the instrument.

Sensitivity: <100 fluorescein molecules can be detected in the green fluorescence channel; forward and side scatter signals from submicron particles are measurable.

Precision: Fluorescence CV <1% on Partec DNA Control standards is guaranteed.

**PA Ploidy Analyzer and CCA Cell Counter Analyzer**

The Partec PA and CCA are one- or two-parameter push button operated desktop flow cytometers using a mercury arc lamp as a light source. The detectors are PMTs; in a two-parameter system, they can be configured to detect fluorescence in two spectral regions or fluorescence in one region and side scatter. The main applications are in cell biology and pathology for cell cycle analysis, apoptosis detection, micronucleus analysis, live/dead cell discrimination, and cell counting.

**8.9 SOME OTHER FLOW CYTOMETER COMPANIES**

**Advanced Analytical Technologies, Inc. (AATI)**

AATI makes the RBD2100, a small-footprint, benchtop flow cytometer, with a red diode laser source, intended for detecting and determining the viability of bacteria in environmental, food, and pharmaceutical samples and for characterizing microorganisms in fermenters.

**Agilent Technologies, Inc.**

Agilent, spun off from Hewlett-Packard, produces the 2100 Bioanalyzer, incorporating microfluidic "lab-on-a-chip" technology originally developed at Oak Ridge National Laboratory by Ramsey et al.<sup>2907,9</sup> and brought to the product stage by Caliper Technologies Corporation. The instrument incorporates a red diode laser and a blue (470 nm) LED as light sources; samples are introduced in dispos-

able “chip” cartridges containing an observation chamber and related fluidics. While the 2100 is intended primarily for capillary electrophoresis, chips are available that allow cell fluorescence to be measured in relatively slow sheath flow. Red fluorescence measurements are reasonably sensitive, with a detection limit of 5,000 MESF for Cy5 and related dyes; as might be expected, only relatively strong green fluorescence signals (>2,000,000 MESF of fluorescein) can be measured when the LED is used for excitation.

### Apogee Flow Systems Ltd.

Apogee now provides service for the **Bryte HS**, the last commercial version of the arc source flow cytometer developed by Steen and Lindmo<sup>100,3</sup>, and recently put improved versions of the instrument, which can measure small and large angle scatter and fluorescence in two to four wavelength regions, back into production.

Earlier versions of this apparatus were sold by Leitz as the MPV-Flow and by Skatron, a Norwegian company, as the Argus. The Argus was, for a time, distributed in Europe by Ortho and in the U.S. by Bruker. The rights to the instrument were then (in the 1990's) acquired by the Italian subsidiary of Bio-Rad Laboratories, a U.S. company headquartered in California. If that genealogy isn't complicated enough for you, here's another interesting wrinkle. Block Engineering, which, at the time, had some of the most advanced flow cytometry technology around, was acquired by Bio-Rad (the U.S. company) in 1977; at the time, Bio-Rad wasn't interested in flow cytometry, and lost an opportunity to become a leader in the field. Years later, they dipped a toe in the water, but, while the Bryte was equipped with an oil immersion lens, Bio-Rad never quite got totally immersed. As of 2002, they are, however, selling another flow cytometer; Bio-Rad is one of a number of companies developing multiplexed flow cytometric bead assays using Luminex's beads and software, and reselling the Luminex 100 cytometer, on which the assays are run.

The MPV-flow was built on an inverted fluorescence microscope, which could still be used as a microscope if you removed the flow chamber from the stage, and incorporated a photometer that could be used for static microphotometry as well as for flow cytometry. The Argus and other later versions of the instrument are assembled on something closer to an optical bench. A syringe pump is typically used for sample injection; cells in sheath flow are observed as they flow along a surface following extrusion from a nozzle. The flow cell in the Argus was open, with the sample stream exposed to air; the Bryte HS and Apogee's instruments can use a newer closed flow cell design.

All generations of this apparatus are demonstrably very precise and very sensitive; production models have shown CV's of less than 2% in measurements of bacterial DNA content, and done very well in characterizing bacteria by two-angle scatter. With a laser source added, the original laboratory-built system was capable of detecting light scatter

signals from single virus particles; production instruments found a niche for work with bacteria. With an arc lamp source, the Argus and Bryte HS could reportedly detect a few thousand fluorescein molecules using blue-green excitation. Like other arc source systems, they could/can readily be changed from UV to blue-violet to blue-green to green excitation simply by changing optical filters; this provides an advantage over benchtop systems with fixed wavelength laser sources. Apogee's arc source **A10** replaces the Bryte.

In the late 1990's, Bio-Rad cooperated with Gary Salzman and his colleagues at Los Alamos National Laboratory, and with Harald Steen, in designing and producing two somewhat miniaturized versions of the Bryte apparatus, intended to be used by the U.S. Army for biowarfare agent detection (O, Gucker, where art thou?). One used an arc lamp source; the other retained the epiillumination optics but used a 532 nm green YAG laser source. Apogee now offers the **A20** for military use (you need a password to get the data sheet) and the **A30** for the rest of us. It uses a volumetric pump for sample feed, measures small and large angle scatter and two to four fluorescence parameters, and is available with a solid-state violet, blue, or green laser source. The A30 can detect scatter signals from medium to large viruses as well as bacteria.

### Bentley Instruments

Bentley's Somacount and Bactocount flow cytometers are designed for somatic cell and bacteria counting in milk. They both rely on fluorescent DNA stains. The Somacount uses ethidium bromide, and doesn't draw enough current to have an argon laser (used in their earlier models), and the Bactocount is said to have a solid-state laser, so I'm guessing they use green YAGs. Food science marches on; there are several other companies in the same business as Bentley.

### Chemunex SA

Chemunex manufactures both a flow cytometric apparatus (the D-Count) and a laser scanning system (the Chem-Scan RDI) for doing total viable counts of microorganisms in food, pharmaceuticals, cosmetics, drinking water, etc. Organisms are classified as viable if they produce and retain fluorescent material after incubation with fluorogenic substrates; many of Chemunex's test reagents appear to be esters of fluorescein or its derivatives, and both the scanning and flow systems apparently use argon lasers. Before they started producing their own flow cytometers, Chemunex was using small arc source instruments from Partec.

### CytoBuoy b.v.

The CytoBuoy<sup>2566,2910</sup> is a flow cytometer with a fairly sophisticated optical and electronic design that is designed to sit in the water and count whatever drifts or swims by - in the size range of phytoplankton, anyway. The company is dedicated to marine biological applications, but the b.v. doesn't stand for “bon voyage”; it's Dutch.

### Delta Instruments bv

Delta is another Dutch company; they make the *SomaScope*, an arc source fluorescence flow cytometer system for counting somatic cells in milk, having started out buying instruments from Partec. Delta's web site also lists a "BactoScope" for counting bacteria, but provides no further information on the technology. If it weren't for the web, I wouldn't know them from Edam.

### Fluid Imaging Technologies, Inc.

From sea to shining sea - the *FlowCAM*<sup>243</sup>, from Maine, is an imaging flow cytometer for continuous monitoring of water; it was used to produce Figure 4-38 (p. 168).

### FOSS Electric A/S

And back from water to milk again. Foss Electric was, as far as I know, the first producer of a cytometric instrument for counting somatic cells in milk. However, the original *Fossomatic* (not, as far as I know, advertised on Saturday Night Live) was not quite a flow cytometer; it stained cells with ethidium bromide and examined them on what might best be described as a rotating slide. The current version, the *Fossomatic 5000*, is a flow cytometer, as is Foss's *BactoScan FC*, designed for counting bacteria in milk.

### Guava Technologies, Inc.

It would be almost poetic at this point if the *Guava PC Personal Cytometer*<sup>245</sup> were designed for food analysis on tropical islands. Nope. The *Guava* is a very small (footprint not very much bigger than the laptop computer that sits on top and runs it) flow cytometer, sold with dedicated reagent kits and software for quantifying protein binding to cells or particles, total and viable cell counting, and detection of apoptotic cells. The flow chamber is micromachined; the system does not use sheath flow, but the chamber is big enough, and the illuminating beam wide enough, to permit cells to be measured at a reasonable rate without frequent clogs. The light source is a green (532 nm) YAG laser; the instrument measures forward scatter and fluorescence at about 575 and 675 nm. Protein binding measurements utilize phycoerythrin antibodies; viability is determined by exclusion of 7-aminoactinomycin D by nucleated cells stained with a permeant nucleic acid dye fluorescing at a shorter wavelength. I have seen the *Guava PC* in operation, but, so far, I haven't gotten hard answers to questions about its precision, which I wouldn't expect to be that good because there is no sheath. I'm guessing you probably wouldn't want to use the system for DNA histogram analysis, but it seems to do its assigned tasks reasonably well, and, while not inexpensive, it is easy to operate, and doesn't take up a whole lot of space.

### Howard M. Shapiro, M.D., P.C.

**Howard M. Shapiro, M.D., P.C.**, is my own corporate entity, in business since 1976. Although we have actually

sold a few *Cytomutts* in the past, and can still probably find you one of our **4Cyte™** computer interfaces (if you have an ISA slot PC to plug it into) and software, instrument production is really not our thing. Most of the systems we have been built have been for research collaborators or for companies interested in developing and producing flow cytometric apparatus. If the next chapter gets your juices flowing, we'd be happy to help you build your own instrument.

### iCyt-Visionary Bioscience

Gary Durack, most recently of the University of Illinois at Urbana, will be happy to build cytometers and/or parts for you, and/or modify your cytometer, and/or integrate it into a larger system, e.g., for high throughput screening. He's got good credentials and experience. We haven't worked together before, but I wouldn't be upset (and I hope he wouldn't) if you paid me for advice and him for hardware.

### International Remote Imaging Systems

*IRIS's Model 500 Urine/Fluids Workstation* and *Model 939UDx™ Urine Pathology System*, are clinical urine analyzers employing real-time video flow imaging cytometry. Particles detected in the stained core stream are photographed by a computer-controlled microscope camera, using a triggered strobe flash. These products include a computer-controlled video camera and microscope assembly that views an optical flow cell. Particles are automatically classified based on size, shape, color, and staining intensity; images of particles are presented on a screen for visual confirmation. Samples are manually introduced into the *Model 500*; the *Model 939UDx* has automated sample handling.

### Luminex Corporation

The *Luminex 100* flow cytometer is a benchtop instrument designed specifically to perform multiplexed ligand binding analyses. I helped *Luminex* design it, and like to think of it, at least as far as optics go, as the first production instrument incorporating *Cytomutt* technology. The beads used for assays are about 6  $\mu\text{m}$  in diameter, and are color-coded by staining with a mixture of two hydrophobic, red-excited fluorescent dyes, with emission maxima at about 660 and about 750 nm. The label used for protein assays is typically phycoerythrin (PE); Cy3 and some rhodamine dyes can be used as nucleic acid labels. Particles are observed at rates as high as 5,000/s as they flow upward in a chamber with a 200  $\mu\text{m}$  square internal cross section, passing through separated 20  $\mu\text{m}$   $\times$  80  $\mu\text{m}$  elliptical focal spots from a 5 mW, 635 nm diode laser and a 10 mW, 532 nm YAG laser. High-dry (N.A. 0.63) lenses on opposite sides of the flow cell respectively image the intersections of the 635 nm and 532 nm beams with the sample stream. Mirrors and dichroics separate side scatter, 660 nm fluorescence, and >715 nm fluorescence signals generated in the 635 nm beam, diverting them to avalanche photodiode (APD) detectors. Fluorescence at

about 575 nm, excited by the 532 nm beam, is directed to a PMT module by a mirror and dichroic; a bandpass filter is placed directly in front of the PMT. Image plane field stops are used with all detectors. The side scatter channel is used as a trigger channel; pulse width information from this channel is used to exclude bead doublets from analysis.

The Luminex 100 was the first production cytometer to implement high dynamic range digital pulse processing. Signals from the APDs are digitized to 12 bits' precision, providing a usable dynamic range of almost three decades; the green-excited fluorescence signal used for assay readouts is converted by a 14-bit ADC, providing almost four decades of dynamic range. Luminex provides data capture software with relatively limited processing capability that can export data to FCS 2.0 files. I and others have found that the instrument can detect <500 PE molecules bound to beads; the red-excited fluorescence channels are less sensitive (detection limits of several thousand MESF), but good enough to do a variety of immunofluorescence measurements, e.g., CD4 lymphocyte counting using only the red laser for excitation, with side scatter triggering and cells bearing CD4-APC being counted within a lymphocyte gate defined by CD45-APC-Cy7 fluorescence and side scatter<sup>2447</sup>. At present, Luminex is working with Bayer Diagnostics toward extending the 100 for use cellular analyses, e.g., CD4 counting. As a general rule, the company sells instruments and beads to partner companies developing bead assays, rather than to end users. But things might change; get in touch with me if you're interested.

### NPE Systems, Inc.

In the early 1980's, Rick Thomas and Jerry Thornthwaite played with a system designed primarily for DNA measurements, eventually forming a company named RATCOM, which, rather than heralding the era of punk marketing, acknowledged that Rick's middle initial is A. The RATCOM Personal Cytometer used an arc source and a photodiode detector, and made electronic volume and fluorescence measurements in a three-sided cuvette flow chamber. It was a benchtop system with an Intel-based personal computer for data analysis, ahead of its time because it used computer-controlled motorized optical mounts to maintain alignment and also implemented high-speed digital pulse processing, albeit with a limited dynamic range due to the relatively low precision of high speed ADCs available at the time.

In the early 1990's, RATCOM received a contract from NASA to develop a flow cytometer to be used on the Space Station, a project initiated by NASA and the Florida Division of the American Cancer Society, which was hoping that spinoff from the project would yield some improvements in cytometry relevant to cancer biology and oncology here on Earth.

Fast forward to 2001 (an appropriate year, what?), when an editorial and three papers in *Cytometry*<sup>2911-4</sup> described the use of an instrument, looking a lot like the pre-NASA

RATCOM instrument but presumably benefiting some from the NASA project, for nuclear DNA and nuclear volume measurement in normal and cancer cells. In this work, the ratio of nuclear volume to DNA content, dubbed the Nuclear Packing Efficiency, or NPE, was shown to discriminate between nonmalignant and malignant cell populations with similar DNA content. Hence NPE systems. As I mentioned, the NPE analyzer appears to have many of the characteristics of Rick Thomas's older instruments, but, as I also mentioned, they were ahead of their time. The instrument is advertised as yielding DAPI fluorescence CVs of <1.4%, not a surprise for an arc-based system. The knock that has frequently been put on arc source systems is that they are harder to keep aligned than laser-based flow cytometers, and getting around that with computer-controlled mounts, which remain a feature of the NPE analyzer, was and still is a good idea. Whether the NPE concept will boost NPE as a company into orbit remains to be seen.

### Union Biometrica, Inc.

Union Biometrica, now a unit of Harvard Biosciences, has developed and sells a series of large particle sorters incorporating their COPAS<sup>TM</sup> (Complex Object Parametric Analyzer and Sorter) technology. The company was started by Peter Hansen, whose experience in flow dates back to the 1970's, when he worked at Ortho, and Petra Krauledat, who worked for B-D for quite a while. Having already sold off another company, which developed a scatter/extinction based flow cytometer to do immunoassays, Peter and Petra capitalized Union Biometrica, which, in its early days, developed a prototype flow cytometric (again, extinction and scatter) veterinary hematology analyzer for another company. They also responded to request to build instruments that could analyze and sort *Caenorhabditis elegans* and *Drosophila* embryos. We're talking big stuff here; the COPAS stream diameters range from 250  $\mu$ m to 1 mm.

Particles flow downward; they pass first through a 635 nm beam, derived from a diode laser, in which extinction and, optionally, fluorescence signals are measured, and then through a 488 nm beam (which, in the newest systems, comes from a Coherent Sapphire solid-state laser), in which fluorescence in one or more spectral regions is recorded. After emerging from the flow chamber, the stream is normally diverted sideways to a waste collector by a high-pressure air jet; when a particle is selected for sorting, the air jet is briefly turned off. The sorting speed depends on the stream size; with a small stream, it is possible to sort several hundred objects/s, but the sort rate for *Drosophila* embryos is only a few dozen/s. This rate appears to be somewhat higher than the rate achieved by Furlong et al<sup>2925</sup>, who, independently, developed and demonstrated a *Drosophila* sorter at Stanford, and it is a great improvement on micromanipulation, which was all that the nematode, fly, and fish embryo biologists had previously had at their disposal for selecting organisms. Union Biometrica has licensed the Stanford technology, although how much of it is incorporated in the

COPAS instruments is unclear. However, if the price tag on the Union Biometrica instruments is too high for your budget, you can get plans to build your own instrument from Furlong et al at <<http://www.stanford.edu/~profit>>.

When I last visited Union Biometrica, shortly after the acquisition by Harvard Biosciences, the plan seemed to be to refine their digital pulse processing technology to permit some degree of information about morphologic detail to be extracted, providing a much higher degree of sophistication in defining sorting criteria. Most of the people playing this game are putting one or more fluorescent reporter proteins into the organisms they work with, and looking for different patterns of expression is a lot more refined, and usually more appropriate, than simply looking for different levels of expression. There was also talk of developing a small (COPAS instruments are built up vertically, and share a small footprint that doesn't occupy much precious lab bench space), relatively inexpensive sorter for the small stuff with which the majority of flow cytometer and sorter users spend most of the time. Since my visit, things seem to have become less "COPASetic" at Union Biometrica; while a recent news article mentioned that Harvard Biosciences was looking to the COPAS line for big profits, it appears that Peter and Petra have taken their money and run.

## 8.10 HEMATOLOGY INSTRUMENTS, ETC.

I'm deviating from strict alphabetical order here because it makes sense to do so; I also won't guarantee that I've found all the manufacturers. If you want more details on these gadgets than appear here, try the manufacturers' web sites and/or the journal *Laboratory Hematology*. There is also a 1995 book by Groner and Simson<sup>2915</sup> on hematology analyzers; it was fairly comprehensive when it appeared, but could probably do with an update, because new and/or improved instruments keep on rolling out.

There used to be a relatively clear dividing line between the fluorescence flow cytometers and the flow cytometers used in clinical hematology labs for counting and classifying blood cells; the instruments in the latter group didn't use fluorescence. Not any more. Three things remain true. The hematology analyzers use a much wider range of physical parameters than you will find in fluorescence flow cytometers; i.e., DC and AC electrical impedance, absorption, extinction, forward, intermediate-angle, and side scatter (polarized and depolarized), and, now, fluorescence, usually for reticulocyte counting. There are also a lot more hematology analyzers than there are fluorescence flow cytometers; **ABX Diagnostics**, a French manufacturer, was recently reported on a trade publication to have a 20% share of the market, and to have sold over 5,000 instruments in 2000. Finally, while the software for hematology instruments does print out histograms and dot plots, the printout also contains the values for counts, sizes, percentages, etc. of various cell types, all obtained without operator intervention.

**Technicon Instruments Corporation**, now **Bayer Diagnostics**, offered the first flow cytometric differential leu-

kocyte counter, the Hemalog D, to the market in 1971, at which time only two companies (Bio/Physics Systems and Partec) made fluorescence flow cytometers. The Hemalog D, and the H-series and later blood cell counters<sup>84,5</sup> from Bayer have been used for extinction and scatter measurements for research purposes<sup>359-60,1609</sup>; they could be used for T cell subset analysis using an immunoperoxidase staining procedure<sup>779,1384</sup>, but were never widely promoted for that application. It is clear that Bayer has the know-how and the production and marketing capability to get into the fluorescence flow cytometer business, and it would not be a surprise to see them come out with an immunofluorescence analyzer.

**Abbott Diagnostics**, which makes the Cell-Dyn series of hematology instruments, remained poised on the brink of producing a fluorescence-based instrument for over a decade. The He-Ne laser-based Cell-Dyn 3000 and 3500 could do leukocyte differential counts based on measurements of multi-angle polarized and depolarized scatter<sup>710,986</sup> (pp. 278-9). A number of people involved in instrument design at B-D moved to Abbott in the days when Abbott was **Sequoia-Turner**, and made only impedance-based hematology counters; the low end of the Cell-Dyn line is still impedance-based. Sequoia-Turner was subsequently acquired by Unilever, which found it too small to provide much Unileverage, and divested it to Abbott. After an elephantine gestation period, Abbott came out with the Cell-Dyn 4000, which retains the scatter measurement capabilities of the lower-end 3200 and 3700 (model number inflation), but has an argon laser source and also measures fluorescence. The 4000 uses fluorescent nucleic acid stains to count reticulocytes and nucleated red cells, and can also do CD4 and CD8 counts with fluorescent antibodies, although, at present, the instrument is doing a "two-platform" analysis in a single box, using separate tubes for cell counts and immunofluorescence.

I mentioned **ABX Diagnostics** before; their instruments incorporate both impedance and optical measurements, including fluorescence. The same is true for **Sysmex**, which started out in Japan as **Toa Medical**, building impedance-based systems, and now makes instruments that incorporate optical measurements, including a dedicated reticulocyte counter and also the UF-100 flow cytometric urine analyzer, both of which measure fluorescence. As of 2001, Sysmex had some marketing arrangements with Roche Diagnostics, which, for a time, was selling its own COBAS line of hematology analyzers, developed, if I remember correctly, in France.

Then, of course there's **Beckman Coulter**, the original (at least from the Coulter side) 800 pound gorilla of hematology instrument manufacturers, and certainly the one most familiar to the majority of fluorescence flow cytometer users. They manufacture a veritable alphabet soup of hematology instruments, including the LH 700 Series, AC-T™ series, HmX, MAXM, STKS™ and Gen-S™. Their higher-end products measure AC and DC impedance and several optical parameters.

The industry is not exactly going to the dogs, but IDEXX Laboratories has just introduced a small but sophisticated hematology analyzer, the LaserCyte™, to the veterinary market. Maybe somebody will run some giant panda blood through one in time for my next edition.

## 8.II LITTLE ORPHAN ANALYZERS (AND BIG ORPHAN SORTERS)

We now find the parent companies of many commercial flow cytometers, if not the hardware, among the dear departed. I have included descriptions of some of this apparatus for historical purposes and for the benefit of those of you who may become big siblings or adoptive parents. None of the instruments involved is apt to be left on your doorstep in a basket; any of them could make you a basket case. However, help is available (see Chapters 9 and 11).

### Bio/Physics and Ortho: Cytofluorograf to Cytoron

If you can lay hands on one of the original Bio/Physics Systems Cytofluorographs (Model 4800, 4801, etc.), give it to the Smithsonian (they already have a B-D FACS). The later model FC-200, which had a rectangular flow cell and more efficient (N.A. 0.45) collection optics might have been worth keeping; it was more sensitive than most stream-in-air systems, if not quite up to the B-D FACScan.

Ortho's System 30 flow cytometer, the direct successor to the FC-200, and the System 50 cell sorter were both built on the same optical bench unit, which was more compact than those used in the early B-D FACS and Coulter EPICS sorters; the system was only slightly larger than the FACScan and Profile. The Ortho flow cytometer could be converted to a sorter, and vice versa, by changing flow chambers and adding (or removing) electronics. These instruments could be equipped with low- (20 mW air-cooled), medium- (100 mW water-cooled) or high-power (2-5 W) argon ion lasers and were always shipped with a second laser as well. In the standard versions, this was a 0.8 mW He-Ne laser, but the systems could be supplied with two ion lasers instead.

An elliptical focal spot(s) less than 10  $\mu\text{m}$  high and about 130  $\mu\text{m}$  wide was produced with crossed cylindrical lenses. Flat-sided quartz flow cells with a 200  $\mu\text{m}$  square cross-section were used for observation in both the flow cytometers and the sorters. In the flow cytometer, the fluidic system was closed; in the sorter, a 75 or 100  $\mu\text{m}$  watch jewel orifice mounted at the bottom of the flow cell, was used to define the jet diameter.

Both forward scatter and fluorescence signals were collected with relatively high-aperture aspheric lenses; on-axis extinction measurements were also made, using the He-Ne beam. Photodiodes were used as extinction and forward scatter detectors, but a PMT could be substituted as the forward scatter detector. PMTs were used to detect fluorescence and orthogonal scatter. The optical geometry permitted fluorescence measurements to be made in the forward direction as well as in the orthogonal direction.

The orthogonal collection lens formed an image of the observation point; field stops were introduced by using fiber optics of small diameter to transmit collected light to detectors (after some 15 years, B-D has, effectively, resurrected fiber optics as relay elements in its LSR II). The orthogonal collection lens could be replaced with the so-called "Ultra-sense" optics, comprising a long working distance, high-dry microscope objective for improved light collection efficiency, and a minifying lens to reduce the image formed by this lens to a size compatible with the fiber optics in the detector system.

The Ortho instruments were the first to permit a choice of pulse peak, integral, and/or width measurements and included log amplifiers, but not very good ones. Kamentsky's hardwired analyzer (see p. 28) allowed definition of two parallelogram-shaped sort windows and counting of cells in selected windows. Ortho originally offered a Tracor pulse height analyzer, and later switched to computer-based data analysis systems. However, in their time, the capacity of the Ortho cytometers to measure lots of parameters was limited by what was (or wasn't) available in the way of computers.

The 2151 (upgraded from the 2150) was, in the late 1970's, the most elaborate and most versatile computer offered by any manufacturer of cell sorters; it was, unfortunately, also the most expensive. It used two Data General MP/200 microminicomputers to do a job now routinely done by personal computers or their equivalents. While it took Ortho's competitors some years to catch up with the 2151's capabilities, Ortho was stuck with a dinosaur by the time they did. Their 2140, a "simple" computer system also based on a Data General engine, didn't help things much, because of its high price and limited capabilities.

A few System 30's and 50's, upgraded with data analysis systems from Cytomation or Phoenix Flow Systems, or with my 4Cyte™ hardware and software, are still in productive operation. B-D supplied parts for the line for several years after the 1987 deal in which it bought out Ortho's flow cytometry business; these days, you have to contact Kevin Becker at Phoenix or scrounge if you need replacement components, and few people do.

I must admit that BD Biosciences' new FACSAria sorter, with its relatively small enclosure and efficient optics, including relay fiber optics, brings to mind – or to my mind, at least – the old Ortho System 50. I'm pretty sure the FACSAria will be a much better competitor in the market.

Ortho's Spectrum III flow cytometer was sold for clinical research applications (sold only to prevent disease?). It used a 100 mW argon laser source and incorporates the flow cytometer configuration used in the System 30, with Ultra-sense optics. The focal spot was made relatively wide to minimize sensitivity to movement of the flow chamber. Forward and orthogonal scatter and red and green fluorescence could be measured.

Both core and sheath fluid were driven by positive displacement pumps; when a sample was presented by the operator, a controlled volume was aspirated through an exter-

nal probe. The Cytoron Absolute (see below) continued that tradition. The Spectrum III incorporated a control computer which, like that in Coulter's old EPICS C, was used for most operator interaction with the instrument, controlling laser power, PMT gain settings, etc. In my limited exposure to Spectrum IIIs, I found them exasperatingly user-unfriendly, because the operator didn't have much control over what goes on.

Ortho's flow cytometer subsystems had the edge over those in other manufacturers' instruments, especially in regard to sensitivity and precision for measurements of very small particles (I've seen single virions in scatter in a System 50), until instruments such as the B-D FACScan came on the scene. Because they were designed for multibeam operation, Ortho's systems, in my opinion, did better at it than did other older systems. That opinion is not, by the way, influenced by the fact that I have had business dealings with Ortho; in the days when the older systems were designed, Ortho never asked my advice about hardware. One could demonstrably<sup>643,645-6</sup> get good results from Ortho systems using low-power light sources such as helium-cadmium lasers. The axial extinction pulse width measurement, also unavailable from surviving manufacturers, provided better sizing than did forward scatter measurements. On the other hand, Ortho's System 50 flow cell design was too complicated, leading to frequent clogging and making it hard to maintain good sorting performance. In the last analysis, it wasn't the quality of its instruments, but the quality of its management, that put Ortho out of the flow cytometer business in 1987.

But not for long. Around the time B-D bought Ortho out, Kevin Becker, who had worked for Ortho, founded Phoenix Flow Systems, which still provides rehabilitative services for older instruments. However, as it turned out, Ortho itself became the first flow cytometer company to rise from its ashes. Ortho's European component, based in Milan, continued to be involved with flow cytometry after 1987, distributing both Skatron's arc source instrument and a laser-based, four-parameter benchtop instrument manufactured in Japan by Omron. In 1992, Ortho brought a refined, five-parameter (two-angle scatter, three-color fluorescence) apparatus, the **Cytoron Absolute**, to the American market. The "Absolute" in the name reflected the instrument's capability for doing absolute CD4<sup>+</sup> T cell counts; it used a calibrated syringe pump for volumetric sample delivery.

The image-forming optics in the Cytoron were similar to those used in Ortho's older instruments; collection efficiency was increased by using a high-aperture (N. A. 0.9) lens. The flow cell was a flat-sided, square (200  $\mu\text{m}$  I.D.) cuvette. An internal computer system controlled data acquisition and could perform some data analysis tasks; later versions of the firmware in the internal system allowed everything to be controlled by a Windows PC.

The Cytoron used an air-cooled argon ion laser for illumination; it was comparable in sensitivity to B-D's FAC-

Scan and Coulter's EPICS XL, but its maximum analysis rate was higher, i.e., 20,000 cells/s as compared to 5,000 or less for the FACScan and EPICS XL. During the mid-1990's, Ortho toyed with the idea of moving to 4-color fluorescence analysis capability and digital log transformation and compensation, even paying me to do some feasibility studies, but their flow operation, first to rise from its ashes, had fallen back by the end of the decade.

### HEKA Elektronik GMBH: The FLUVO II Analyzer

HEKA sold the FLUVO II flow cytometer developed by Kachel<sup>66</sup>, an arc source instrument that measured electronic cell volume and fluorescence in two or three wavelength regions. The optical system of the FLUVO II was basically that of an inverted fluorescence microscope; illumination and collection were done through an immersion objective. The flow system utilized a "tubeless transducer"<sup>349</sup> into which cells were introduced through a hole in the bottom of the sample container; the time taken for cells to reach the observation point was thus minimized, facilitating kinetic studies.

HEKA also sold Kachel's Z-80 based CYTOMIC 12 system<sup>620</sup> for one- and two-parameter data analysis; the later, PC-based "Cyto-Disp" computer supplied with the FLUVO II had a software suite that included Valet's "Diagnos 1" program for automated cell classification<sup>874</sup> in addition to more conventional programs.

### The Kratel Partograph

The Partograph flow cytometer followed a design by Eisert<sup>168, 616-9</sup>. A flat-walled flow chamber with dual sheaths provides an extremely stable flow pattern. Two laser beams are focused through the same high-dry microscope objective which serves as a fluorescence collection lens, producing separated spots as small as 1  $\mu\text{m}$  in diameter. When these spots are used for fluorescence measurement, integration of the fluorescence signal is required for quantification of total fluorescence in cells. However, considerable information is available from the pulse shape. The unique feature of the Eisert design lies in its capability to make absolute measurements of cell diameter from extinction pulse width; this is done by using the interval between a cell's traverse of the first and second illuminating beams to correct the raw value of pulse width for variations in cell velocity.

The Partograph FMP was available with low-power (15 mW) argon and/or He-Ne laser sources; an arc lamp source and sorting capability were also offered. The instrument fit on a benchtop. The computer systems used for data analysis were built around the Tandy (Radio Shack) TRS-80 (Z-80 chip) and, later, around a PC/AT compatible. Kratel also sold Kachel's CYTOMIC 12, later available from HEKA.

### The ODAM ATC 3000

The ODAM ATC 3000 was a multiparameter cell sorter developed in France<sup>2916</sup>. It could use one or two ion laser sources; the flow chamber incorporated an electronic

cell volume measurement orifice in addition to a sorting orifice. The instrument's most unusual feature, however, was its use of a toroidal lens for light collection. As many as six signals (pulse height or integral, linear or log, and linear combinations or ratios) derived from the cell volume sensor and 3 PMT detectors could be processed by a 24-bit data analysis system built from bit-slice microprocessors. The computer system, available separately, could be programmed in Pascal by the user. The apparatus provided investigators in France with a native alternative to imported flow cytometers; I don't know of any being brought to the U.S. Bruker Spectrospin, S.A., distributed the ATC 3000 for a while; they were also, briefly, the U.S. distributor for the oft-abandoned Skatron Argus. Bruker eventually gave up flow cytometry to concentrate on their core business, which is high-ticket NMR and spectroscopy apparatus; I guess flow cytometry was just a sheath business.

### Also Among the Missing

Three Japanese companies, **JASCO**, **Omron**, and **Showa Denko**, have made flow cytometers. I saw a paper in Japanese describing Showa Denko's apparatus, an argon laser source cell sorter. I don't know anything more about that instrument. JASCO's laser source benchtop analyzer was competitive with the EPICS Profile and FACScan; it was looked at by at least one American company, which decided not to pursue it for reasons not related to its performance. Omron's instrument became Ortho's Cyturon Absolute on the way to the orphanage.

Fred Elliott, who designed some of the innards of the Ortho instruments, started a company called **Cyto-Diagnostic Systems**, and developed a small laser source flow cytometer, with a data analysis system built around a PC/AT-compatible microcomputer, in the mid-1980's. The instrument was competitive at the time, but a deal for production and distribution was never made.

### Flow Cytometer Rehabilitation; Used Instruments

There is a reasonably brisk trade in used flow cytometers and sorters. It is generally possible to get service and parts, at least for relatively recent models, from the manufacturers themselves, provided the manufacturers are still in business. **Phoenix Flow Systems** has made something of a specialty of rehabilitating old instruments, and they and Cytomation provide (past tense for Cytomation) add-on replacement computer systems for data analysis and, in Cytomation's case, for sort control, as well. **Applied Cytometry Systems** also provides replacement computers for some instruments. My (that is, **Howard M. Shapiro, M.D., P.C.'s**) **4Cyte™** data acquisition hardware can also be used with older systems, if you can find a PC with an ISA slot into which to put the hardware. Once you've got a new computer system, and associated data acquisition software that can generate list mode and other data files in the Flow Cytometry Standard (FCS) format, you can use software from a variety of third-party providers for data analysis.

### Following Suit

Bio/Physics Systems, later Ortho, was the first U.S. company to make fluorescence flow cytometers. As other manufacturers followed suit, suits followed. Ortho sued B-D, Coulter, and Technicon for infringing on various patents; B-D settled in connection with the 1987 deal. Technicon beat Ortho. It all took years. I wish I had five percent royalties on the legal fees.

These days, it seems as if everybody is suing everybody else. Judges and juries are being asked to decide complex technical issues; a dartboard might give better results. To make things worse, the patent examiners, who are overworked (and who, with one notable exception, are no Einsteins), are primarily interested in seeing that two individuals aren't both given patents for the same invention. To forestall this, they only have to search the patent literature; there's no need to read the journals.

As a result, Joe Schmo can get a patent on something that was published in the open literature in 1899 (even when patent examiners do literature searches, they only look at what's been computerized). This gets licensed to BioScam International. Sam Pull, at Ponzigen, then brings out a product based on the 1899 technology, which he figures is in the public domain. BioScam promptly sues, and the suits at Ponzigen decide to pay BioScam royalties, because it's cheaper than going to court. Meanwhile, in Milan, GenItalia, which had come up with a better version of the Ponzigen method, abandons it because it will be even harder to fight BioScam in court now that Ponzigen is paying royalties for a patent that shouldn't be worth diddly. No wonder my son went to law school.

The legal battles are starting to screw up science. I've told dozens of people who have inquired about sorting eosinophils that the easiest way to do it is to use polarized and depolarized scatter measurements, as described on pp. 278-9. However, as I mentioned back there, the patent on this technique is held by Abbott, which doesn't even manufacture sorters. If people who now work for BD Biosciences (and Leon Terstappen, who originally developed the method, did work for B-D for years) or Beckman Coulter or DakoCytomation tell their sorter customers to use polarized and depolarized scatter, they face suits by Abbott.

If you wait long enough (it's 20 years, now), the patents will expire and you can do what you want. That mode of operation, however, doesn't make for rapid progress. We may get some improvements in the system over the next few years because the software and biotech/pharmaceutical industries, which are vastly more economically significant than our little backwater of flow cytometry, have got the same problems we have and more. I can't wait.

One expired patent that may be of particular interest to the flow cytometry industry is Ortho's patent on Friedman's acoustic cell sorter<sup>126</sup> (see pp. 264-5). This is a closed fluidic system sorter capable of isolating several hundred cells/s, a rate similar to that achieved by the fluidic sorter in B-D's

FACSCalibur. The acoustic sorter, however, unlike the mechanism used by B-D, only diverts fluid into the sort stream when cells are being sorted, meaning that rare cells can be sorted without being diluted by a large volume of extraneous fluid.

## 8.12 THIRD-PARTY SOFTWARE

The adoption of the FCS file format made it feasible for various third-party developers to write and sell, or, in some cases, give away, programs for analysis of flow cytometric data. A market for such software existed, and exists, because peoples' preferences in software tend to be idiosyncratic, and because the third-party programs generally have at least a few features which are not included, or not as well implemented, in software from the manufacturers.

This is not to knock the manufacturers' software; manufacturers, however, tend to have more people writing software than do the third-party companies, and breaking software projects into chunks, while sometimes necessary, almost always results in chinks between the chunks when the overall program is put together. If one good programmer can write the whole program, it's apt to run more smoothly.

I know most of the people who write third-party software, and almost all of them have a lot of experience with and knowledge of flow cytometry. A third-party program is generally written by one such person, and its features and performance characteristics are, as a result, tailored to meet the needs of a demanding user. The programmers writing for the larger companies may know a fair amount about flow cytometry, and may actually be better computer programmers than the third-party developers, but, even if they are working to specifications set by sophisticated, demanding users, it's not quite the same.

Third-party software can get pretty elaborate, especially with hardware added. Both Applied Cytometry Systems and Cytomation, for example, reverse engineered the relatively tight interface between the B-D FACScan and the Consort 32 computer system, which was normally essential for the cytometer's operation, and came up with replacement computer systems and software using Intel processors.

As flow cytometers tend increasingly toward digital signal processing and multiprocessor operation, and as hardware and software combinations replace hardware in the innards of the machines, there will be an increasing amount of software that will, of necessity, remain in the domain of the instrument manufacturers. For everything else, and, certainly, for any manipulation of data already collected in standard file formats, there will be third-party software. If you're satisfied with the software your manufacturer supplies, you may never need anything else. As it happens, though, even the manufacturers are beginning to realize that it takes time and costs them money to reinvent the wheel, and they are making deals with the third-party developers for versions of many of the better software packages which will interface smoothly with the manufacturers' software.

In the area of clinical instruments, the Food and Drug Administration (FDA, not to be confused with fluorescein diacetate) has regulatory authority over software; the software itself has to meet certain specifications. It is to be hoped that the FDA will recognize the benefits of the cooperative approach to software development mentioned above.

You can pretty much get the same data analysis capabilities in third-party software as are available from the manufacturers, and more. A list of third-party developers and some of their offerings appears in Chapter 11. Almost all of the producers offer demos, or at least showcase their products' capabilities on their web sites, so it's fairly easy to find out both whether a particular piece of software does the manipulation(s) you need to do and whether the way in which it does it/them fits with the way you think.

The committee that keeps up the FCS standard has been threatening to release some code for reading and writing FCS files, which may be (certainly is, when I wear my programmer's hat) the hardest part of a flow cytometry data analysis program to code. It would be kind of nice to have a public domain toolkit of program building blocks with which moderately sophisticated users could put together their own *ad hoc* programs. The DOS-based Forth software I wrote had some of this capability, but, at least in my limited experience, it has not been possible to duplicate the critical features in either a Windows or Macintosh GUI.

## 8.13 THE SELLING OF FLOW CYTOMETERS: HYPE AND REALITY

If you listen to the people who sell flow cytometers, you'll be forced to conclude that none of them works. Each manufacturer's people will tell you that the system they sell is the only one that really does work; a chorus from all the other manufacturers will deny this is so. The manufacturers may unite in denunciation of laboratory-built instruments.

If you listen to the people who use flow cytometers, you'll find that all of them work, and that none of them always works. You'll also find that one group of people thinks that one manufacturer's product is easiest to use and most trouble-free, and other groups argue just as passionately in favor of products from other manufacturers.

For example, people with a lot of experience with a B-D instrument always seem to be able to coax better performance out of it than can somebody who is used to other flow cytometers. I had an Ortho System 50 in my lab for a while; the Ortho people, or some of them, who worked on it could always get it to produce sharper DNA content distributions than I could, and I was always able to do better with my Cytomutt than they could. I look at the manufacturers' published precision specifications with a jaundiced eye, because my inquiries indicate that there is a substantial difference between the best that an instrument can do and its level of performance in routine use by the average operator.

If there weren't so many half-truths and misconceptions flying around as a result of manufacturers' and partisan users' efforts on behalf of their machines, it would be easier for

people to choose the flow cytometers, bought or built, which they needed for their particular applications.

If there is one thing about flow cytometers that isn't the same the whole world over, it probably relates to user preferences in light sources. Arc source instruments have done much better in Europe than in the United States, where people prefer lasers. I would have to ascribe this to the fact that many users and potential users in the United States aren't as well trained in the use of fluorescence microscopes as are their European counterparts, and thus can't get the same good results with arc source systems.

If somebody gave me as much money as I wanted, and insisted that I spend it on one commercial flow cytometer, I'd have a problem. My decision would probably be influenced by the same factors that influence my purchases of bicycles, cars, computers, and stereo equipment. I always study the products in great detail, evaluate their performance features, and discover that none of them has all the features I want. I can't build cars; I end up buying the one that feels right. It's the same way with most software; I write my own software for flow cytometry data analysis, but, when it comes to word processors, spreadsheets, drawing packages, etc., I have to buy the one that feels right. With bicycles, computers, stereo equipment, and flow cytometers, I usually have more freedom of choice. I wouldn't like to spend a over a half a million dollars of taxpayers' or investors' money on a piece of equipment because it felt right, but, under the circumstances I just described, I guess I'd have to.

Over the years, we have seen convergent evolution in the development of commercial flow cytometers. If you can get some bell or whistle from one manufacturer, you can get its equivalent from another. Buying decisions tend to hinge on how well you like the user interface, but are also influenced by how well you like the salespeople and/or the local service representatives. Clear edges in performance get harder and harder to find, and manufacturers tend to bring instruments up to spec. That's nothing to complain about.

Over the next few years, there will probably be as many developments in the area of data analysis as in flow cytometric hardware. As more third parties become involved in the generation of hardware and software products for data analysis, users will have more options and more opportunities to tailor the user interface to their own tastes. That's also nothing to complain about. If you're not writing your own data analysis software, you definitely need to find software that feels right. That's why I haven't devoted more space and time to the particulars of this and that software package; what's important is it's not what the program does, but how comfortable you feel with the interface.

The one rule which is most important in deciding which flow cytometer to buy hasn't got anything to do with hardware *per se*. It is, instead,

*Shapiro's Eighth Law of Flow Cytometry:  
Know Thy Cells!*

You really don't want to lay out a lot of money, even if you, as a taxpayer, only contribute a minuscule share of it, for an instrument that won't let you do the analyses and/or experiments you need to do. The manufacturers will, almost without exception, let you run your samples through one of their instruments when you're in the process of making a buying decision. You shouldn't be making a buying decision unless you know enough about flow cytometry to know what cells you're going to be looking at and how they'll be prepared, and what kinds of data analysis you'll need to do. This is especially important if you're looking at something out of the ordinary. If you're trying to sort very big stuff, or very small stuff, be sure the machine can do it. If you're looking for very faint signals, try before you buy.

I have summarized the characteristics of a lot of general- and special-purpose flow cytometric equipment in the previous sections of this chapter; some of the manufacturers provided more information than others. I'd be surprised if I didn't make at least a few mistakes. As most of the manufacturers know, I have always been and still am willing to make corrections in public, in speech, prose, and/or verse. And, for this edition, the corrections should be posted on the web site.

#### 8.14 APPLYING FOR A GRANT FOR A CYTOMETER

Unless you're a very wealthy amateur, have access to lots of industrial money, or hit the lottery, you're going to have to ask somebody for the wherewithal to purchase a flow cytometer. If you work in the United States, that somebody is usually the National Center for Research Resources at the National Institutes of Health, and the mechanism by which you ask for the cash is most often an application for a Shared Instrumentation Grant. To qualify, three or more NIH-funded Principal Investigators have to demonstrate a need for, a capability to use, and an institutional commitment to supporting a "single, commercially available instrument or integrated instrument system" that costs at least \$100,000 (the maximum award is \$500,000). The funding mechanism covers a lot of high-ticket gadgetry in addition to flow cytometers, e.g., NMR equipment, confocal microscopes, and electron microscopes, so you're not just competing with flow cytometry people.

As you might expect, I occasionally sit on panels that review applications requesting funding for cell sorters and flow cytometers; from what I hear from colleagues who sit on similar panels covering the other high-priced toys, the things that weigh for you and against you are pretty much the same there as well. In the rest of this chapter, I'll try to save you some grief if you're writing a grant application for an instrument, to NIH or elsewhere.

There are usually a few dozen applications in any given cycle, of which the four or five given highest priority, and maybe not even those, will get the money. All of the applications, as I mentioned above, are coming from investigators who have already been through the peer review process, and

have gotten the funds to do their research. The review panel is not allowed to consider or question the underlying science; what is at issue is not whether the applicants know immunology, or genetics, or cell biology, or whatever their primary fields of interest may be, but whether they demonstrate an understanding of what to do, and how best to do it, with the equipment for which they are seeking funds. All of the applications are meritorious; however, they can't all be funded. What happens is that those that survive are those with the fewest obvious faults. I can tell you what some of those faults might be, and if you are writing or assisting in the writing of a grant application, you can at least try to avoid them.

The grant, if you get it, pays for the instrument; it doesn't pay for service contracts, operators' salaries, or any modifications to the site needed to install the instrument (it may cost thousands of dollars to bring in the power and cooling water connections for a big laser). Almost everybody who runs a shared instrument facility charges user fees, which are supposed to defray some of those costs. Almost everybody who has run a shared instrument facility knows that the facility is likely to run at a loss. If the administration at your institution doesn't come across as wildly enthusiastic about providing all funds necessary to make up the difference, you're apt to lose points, because somebody else's administration will look better.

It's advisable for the Principal Investigator (P.I.) on a cell sorter grant to be a person who knows a lot about flow cytometry. It is not required that he or she have an NIH grant, as long as there are three potential users who do have NIH grants and are Principal Investigators on those grants. NIH Policy is that the Principal Investigator on a Shared Instrumentation Grant doesn't even have to be a user of the instrument. However, in my experience, reviewers take a dim view of applications in which people with little or no expertise with a sophisticated instrument are listed as Principal Investigators.

In the old days, when there weren't user-friendly benchtop systems around, the graduate students and postdocs had to hang around the sorter lab, even to do simple analyses, and, at least on paper, it was easy to look knowledgeable. Now, a lot of people do a lot of respectable flow cytometry on benchtop systems, which is fine. However, if the P.I. on an application asking for a big sorter with four lasers is somebody whose experience appears limited to benchtop systems, it's a sure bet that that application won't look too strong in comparison with others.

The manufacturers are all too happy to write quotations according to which they will sell you a big sorter and a

benchtop instrument (which will, of course, work together as an "integrated instrument system") for just under \$500,000. I personally wouldn't ask for two instruments. You'll be very lucky if you get one instrument funded; leave some money for somebody else. It won't help your application if any of the reviewers gets even a fleeting impression that you're a pig.

If you have an instrument and are requesting an additional instrument, it helps to be able to show that what you've got is used a lot, which probably means nights and weekends; if you want to replace an old, obsolete instrument, bear in mind that most of us don't think a three year old cell sorter is obsolete because a new model has come out. Also, don't ask for more – or less – instrument than you need. If you're requesting an argon laser, a mixed gas laser, and a dye laser, it helps to include some details of the parameters that will be measured and the probes that will be used, because those lasers are expensive. The same goes for other add-ons. If you don't explicitly justify the need for them, they'll get axed from the budget. If you do get funded, you'll be short of cash, but, let's face it, if you do a poor job of justifying what you've asked for, you're less likely to get funded.

If you announce your intention to do experiments with Hoechst dyes, DAPI, or indo-1, but you have only asked for a single 488 nm argon laser, which doesn't emit the UV light needed to excite these dyes, you don't win points for trying to save money; it simply looks as if you don't know what you're doing.

Some instrument manufacturers will be happy to sell you various computer peripherals at substantially higher prices than you'd pay at a computer store. Having these items in your quote probably won't reduce your overall chance of getting funding if your application is otherwise perfect, but the budget is very likely to get cut, as it should be.

These days, applications are getting so thick, what with biographical sketches and information on other projects for all of the investigators, that many people seem to be skimping on the details of what will be done with instruments. Being concise can be a virtue; being concise to the point at which it becomes unclear that you need or can competently use the apparatus is a vice.

Finally, if you don't get funded the first time, and decide to resubmit the next time around, pay attention to the critique of your application. It's likely to call attention to some of the faults I have just mentioned. If you don't fix everything, your next application won't do any better than your first one. If you do, at least you've got a fighting chance. Good luck.

This Page Intentionally Left Blank

# 9. BUILDING FLOW CYTOMETERS

I am not going to tell you how to build flow cytometers. Not here, not now. The Third Edition of *Practical Flow Cytometry* represented a radical departure from the two previous editions and from their predecessor, *Building and Using Flow Cytometers: The Cytomutt Breeder's and Trainer's Manual*, which contained complete plans for the mechanical, optical, and electronic components of a multiparameter instrument using a 488 nm laser source. Wiley did the math and figured that, since only about one percent of the people who bought the First and Second Editions built machines, it made sense to kill the 50 pages of plans and devote more space in the Third (and this Fourth) Editions to how flow cytometers work and how to use them. I didn't argue.

In his Foreword to the Third Edition, Len Herzenberg suggested that biological scientists really shouldn't be thinking about building flow cytometers. That was easy enough for Len to say in 1994, but neither this book nor the previous versions would have been written if he hadn't felt differently in the mid-1960's. And I noted that the last issue of *Cytometry* I got before the Third Edition went to press in 1994 contained an article about a multidimensional computerized sort control method implemented in the Herzenberg lab<sup>1740</sup>, and not on unmodified commercial equipment, either. Even now, Len always wants to measure more parameters than can be measured with the fanciest commercial flow cytometers, and he always has a few people in his lab building or modifying apparatus with that goal in mind.

## 9.1 WHY BUY A FLOW CYTOMETER?

In principle, you buy a flow cytometer because you want an instrument with a proven design, established reliability, and performance better than you could obtain from a system you might build yourself. You're willing to pay for this, and

also willing to pay some more to insure that a trained service person will keep your instrument in good operating condition and fix it when it breaks.

A well-known analytical cytologist (Bas Ploem) told a bunch of people at a 1981 meeting that "Everybody who has bought a cell sorter up until this time has bought an instrument in development". I would tend to agree with him. It's been my experience that, during the first six months, at least, you're either having fits or having retrofits 90 per cent of the time. That may not be the case with modern benchtop systems, but it still seems to hold for the larger instruments.

Once the operating pattern gets a little stabler, you find that down time comes from annoying little things, such as clogs that require that you remove, clear, and replace the flow chamber, necessitating a fairly extensive realignment of the optics, and from real disasters, such as incineration of laser power supplies, which the laser manufacturer's people rather than the flow cytometer manufacturer's people usually end up fixing.

Even with those minor headaches, there's no question that if you are relatively new to this field, and you want to do something that has been done before, which a lot of people are now doing routinely with commercial flow cytometers, and you have the money to buy and maintain a commercial instrument, you should buy one. This is particularly true if you are interested in sorting; it is a good deal easier for an ingenue to build a flow cytometer than a cell sorter.

## 9.2 WHY BUILD A FLOW CYTOMETER?

Flow cytometers, like many other types of instruments, sell for anywhere from three to five times the cost of the parts which go into them. This is not to say that the manufacturers are making unconscionable profits; some of

them aren't, or weren't, making any profits at all, at least on flow cytometers. It's just that when you factor in the labor costs, plant and equipment, marketing costs, etc., you end up with that multiplied figure. If you have yourself, or your graduate students, or a knowledgeable tech or two, or some other unsuspecting confederates, around as a source of labor, and some minimal shop facilities, like a small drill press and some hand tools, you can count on being able to build a facsimile, you should pardon the expression, of a commercial instrument for a parts cost no more than a third of the selling price. Should you try to do that?

Suppose you already have a sorter, and it's overloaded, and you'd like another instrument? You're no longer new to the field. If you've kept your sorter running, you've undoubtedly had to clear a bad clog and realign the system, and, if you can do that, you're not far away from being able to build your own flow cytometer or sorter. Again, if you can afford to buy another system, you might think about it. What you might conclude, though, is that what's on the market is pretty expensive.

If you'd like a five-beam, benchtop system just for analysis, there isn't a manufacturer making one. If you want a really slow flow system to analyze DNA fragments and viruses, ditto. Nobody blames the manufacturers for being in business to make money. If Len Herzenberg and his colleagues hadn't built the original fluorescence-activated cell sorter and shown that useful things could be done with it, generating a demand, nobody would be manufacturing sorters.

The problem is that today, when most of the companies in the business are big companies, fewer and fewer of them are willing to take a flyer on building something to meet the offbeat needs of a small user community. Most of the manufacturers are making their money selling benchtop systems and reagents, and, while they like to compete with one another, they don't like to compete with themselves, which usually means you have to buy one of their bigger, more expensive instruments if you want maximum flexibility. If you want to do unusual things that neither the benchtops nor the big machines can do, you have to think about building an instrument yourself, or of having someone (present company not excepted) build an instrument for you.

The funding situation being the way it is, maybe you don't have the money to buy a commercial system, even if you work in industry. Then, if you want a flow cytometer, or another flow cytometer, building your own may be the only option.

### 9.3 LEARNING TO BUILD YOUR OWN

Take my word for it, building flow cytometers isn't all that hard to do, and, at least until recently, it kept getting easier, as it became possible to buy bigger and bigger chunks of the do-it-yourself kit ready-made.

The annual research course on flow cytometry (see p. 67) usually features a hands-on lab in which three or four participants assemble a two-parameter fluorescence flow cytometer in an afternoon under the auspices of a couple of people from Los Alamos. It doesn't take much longer to do the same thing in your lab or basement. It can even be fun. Terry Fetterhoff and Bob McCarthy and their confederates described their experience with building and using a Cytomutt<sup>1021</sup> some years ago, when a lot of soldering was required; one of my more recent star pupils, Dennis Way<sup>1741</sup>, got a four-parameter system running in a day and a half, and published on what he did with the instrument, not how he built it. That system has been run for at least ten years, and I've only been called about problems with it two or three times; the last time I checked, Dennis was likely to get lower CVs for beads and DNA standards than I did.

I had originally planned to update the do-it-yourself parts of the Second Edition and publish them on my own, as a sequel to *Building and Using Flow Cytometers*; so far, I haven't gotten around to doing that. The big problem is that I would have to revise the electronics and computer sections almost completely.

On the plus side, flow systems and optics haven't changed all that much since the 1980's; we have pretty much the same mounts, lenses, dichroics, filters, etc. now that we had then. There are a whole bunch of new lasers now available, including UV, violet, blue, green, and red diode or solid-state sources. There are also now PMT's on the market with higher red sensitivity than we used to be able to get, and they are available built into easy-to-use modules with integral high voltage supplies.

On the minus side, while electronics and computers have improved tremendously, it has gotten much harder to prototype and build your own circuits; most devices no longer come in packages that plug into sockets. Instead, you have to get somebody to build you a multilayer circuit board with all of the surface-mounted active electronic devices on it. That costs money. Computers and DSP chips and data acquisition systems are faster and more sophisticated, but software development has gotten harder rather than easier.

In the late 1960's, when I built my own audio systems, they were better than anything I could have bought; that was also true, at least to some extent, of the cytometers I built through the mid-1990's. Today, there's no way I can build audio equipment as good as what I can buy for a reasonable price, or flow cytometers as good as those you or I can buy for what may seem like an unreasonable price. I am still interested in building small, efficient, affordable instruments to do jobs that don't demand all the bells and whistles, and still trying to figure out which of the available component parts are best for doing the job. When I do, I'll probably post the plans on a web site and/or run a course; it's got to be easier than writing books. In the meantime, if you're looking for advice, I'm not hard to find.

# 10. USING FLOW CYTOMETERS: APPLICATIONS, EXTENSIONS, AND ALTERNATIVES

The successful application of flow cytometry in biological and medical research and in clinical medicine depends as much upon understanding of the biology of the systems being studied as upon familiarity with hardware, reagents, and methods of data analysis. Two editions ago, I wrote “It would be futile for this author and this book to attempt to provide even a rudimentary discussion of all of the areas of biology in which flow cytometry is used or of the biological problems to which the technique is applied”; the range of applications continues to expand.

The first flow cytometers were built and run in a few labs committed to instrument development. In the early days, almost any experiment that could be done with a flow cytometer would produce new information; in order to get the experiment done, it was frequently necessary for the experimenter to make a substantial refinement on existing technique.

During the 1980’s and 1990’s, flow cytometry became (not inappropriately) a mainstream technology, with one result being that most of today’s users are trained in biology and/or medicine rather than in instrumentation. The number of papers and the range of journals in which they appear are large enough so that you can’t just look under “Flow Cytometry” in MEDLINE or other databases and hope to find them all, as I pointed out in Chapter 2.

The range of parameters and probes in common use has also expanded considerably since the last edition was published. I’ve tried to cover as broad a range of parameters and probes as possible in Chapter 7, and to at least give some idea of the existing and potential applications of each. I therefore decided to approach this chapter as I did in the last edition, i.e., to consider the few basic tasks and procedures underlying almost all of the **applications** of flow cytometry, and then survey and comment on selected applications and point the reader to articles in which specific techniques and

applications are discussed in detail. But, this time around, I also felt it was necessary to include some discussion of **extensions** of flow cytometry, involving instruments with characteristics and capabilities not yet available in commercial systems, and of **alternatives** to flow cytometry, notably scanning and imaging cytometry, which have become more practical and, in some cases, more affordable since the last edition appeared.

If we achieve our respective objectives in writing and reading, you should, by the end of this chapter, be able to make sense of, and sense nonsense in, anything in the literature which deals with flow cytometry.

## 10.1 THE DAILY GRIND

### Keeping the Instrument Running: Diet and Exercise

In flow cytometry, it is not only “Garbage in, garbage out,” but also “Garbage inside, garbage out.” There are a few tricks to keeping flow cytometers running well, and there’s more to calibration and standardization than running beads through the system. If the instrument isn’t kept in shape, though, it is equally unsuited to any and all possible applications.

Generally speaking, the materials which go into a flow cytometer are air or gas, water or saline, plastic beads and/or samples which contain protein, carbohydrate, fat, and chemical additives such as coloring materials. We run on a similar mixture, beads generally excepted, and, like flow cytometers, are susceptible to pollutants in what we take in.

If your flow cytometer needs an air or gas line input, it’s essential that the air be oil- and particle-free; if you’re not sure, it’s best to have a filter in the line. Even if you never plan to do sterile sorts, and only use water as sheath fluid, it’s advisable to have the water go through a 0.47  $\mu\text{m}$  filter before you put it into your sheath tank or bottle, and not a

bad idea to keep a filter of the same pore size in the line between the sheath tank and the flow system.

If you work with microorganisms, platelets, or other small particles, your sheath fluid and reagents should be passed through a filter with a smaller pore size, e.g., 0.22  $\mu\text{m}$ . If you run using an in-line filter with pores this small, either use a fairly large area cartridge filter or replace a smaller filter frequently, because the pores clog up, resulting in a substantial pressure drop across the filter, which will screw up your flow rate. For the most demanding work, e.g., trying to look at viruses or other really small stuff, you should consider preprocessing your fluids through an 0.1  $\mu\text{m}$  filter; it is tricky to use these in-line, because the resistance is high enough to slow your fluid flow considerably.

Numerous problems may arise due to the tendencies of organic materials in samples to stick to metal and glass as well as plastic tubing in flow cytometers. On a within-day, sample-to-sample basis, dyes such as acridine orange, ethidium and propidium, and the cyanines may wash off the tubing and stain cells to which only fluorescent antibodies had intentionally been added, giving false positive staining. The dyes are usually removed effectively by rinsing the system with chlorine bleach; however, I have been told that the calcium ionophore ionomycin isn't always removed by a single chlorine bleach treatment.

When the bleach itself isn't washed out or neutralized, and you then try to do membrane potential or calcium probe studies on live cells, you find the cells dying instead of dyeing. When doing such experiments, I usually follow the bleach with 50% ethanol and then saline; this may be superstition, but it generally avoids the cell kill I might see otherwise.

On a long-term basis, protein residue can screw up the optical quality of cuvette windows, cause flow disturbances, and provide a food source for microorganisms, which will happily grow in a flow cytometer if they are not frequently disturbed. The best preventive medicine for the ills just described is plenty of fluids. If you start up a flow system that hasn't been run for more than a few weeks, count on spending the first day unclogging it every five minutes. If they're painting the lab, run the flow system every day anyway, if you can, and never shut down at the end of a day without making sure that you've cleaned the flow system out with a purge of bleach, optionally followed by alcohol, and then by a lot of water, with backflushing so you get any residual bleach and/or alcohol out of the nooks and crannies.

Ion lasers, like flow systems, need their exercise; this may be truer of the big lasers than of the small ones. If you have a system with a big laser, you're apt to get into keeping mirrors tweaked and clean, checking on and fiddling with gas pressure, etc.; if you use a small argon laser, you're free from most of those headaches. It's advisable to monitor laser power output if you can; this is straightforward on big lasers, where you shift back and forth between current and light control mode. On smaller lasers, which are usually operated in a light control mode, what you need to do is let the laser

warm up and check the operating current, which will creep up as the plasma tube ages and may scurry up if the optics get dirty or the alignment is knocked out of whack. You will also get clues that you're losing laser power from having to keep turning the PMT gains higher and higher to measure the same particles and/or the same cells stained with the same reagents, even though the system is well aligned and the CV's are low. Laser noise is an uncommon, or at least not a widely reported, problem in flow cytometers<sup>876</sup>; you should be aware it exists but there's no need to go looking for it unless you're getting high CV's for which you can't find another explanation. I mentioned on pp. 142 and 147 that He-Cd lasers particularly need exercise; left idle, they develop increased helium pressure, which makes them get very noisy.

There isn't any exercise for the optics of your flow cytometer, which may get dirty, particularly if your lab is dusty or smoky. Clean living prevents problems; once they're there, you need live cleaning.

### Particulars: Drawing a Bead on Flow Cytometer Alignment, Calibration, and Standardization

Flow cytometers can be calibrated either with synthetic standard particles or with cells or other biological material. It would be nice to have standardized calibration particles that would yield the same results for every user and every instrument, assuming proper alignment of each. We're not quite there, but we have reached a point at which it is possible for careful people using different instruments in different labs to analyze the same specimens and get both qualitative and quantitative results that are in good agreement.

This doesn't happen when the instruments are not in good working order, and there's not much point in analyzing samples on an instrument that isn't. So, as a general rule, it's a good idea to make sure that your flow cytometer is up to snuff before you invest time and money in preparing and running samples. If performance is substandard, you or somebody more skilled and knowledgeable will need to align and adjust the instrument. Since most modern flow cytometers make no provision for the user to adjust the mechanical, fluidic, and optical components, that may mean a service call, which will cost you money, and, even if you or somebody in your shop does the work, you really have to define what's broke before you or anybody else can fix it. As to how to do that, I have only one word for you – plastics.

It is, in principle, possible to produce spheres of polystyrene or other plastics that are extremely uniform in size, and to introduce fluorescent material into such spheres in a precisely controlled manner. It is also, in principle, possible to produce great sweet wines from Gewürztraminer, Riesling, and Semillon grapes. In practice, the sweet wines produced from those grapes are not all cast in the same mold. So it is with calibration particles. The good vineyards do not bottle the bad vintages; the manufacturers do not sell the really bad particles. A good vintage, or a good lot, depends upon fac-

tors not entirely under the vendor's control. People hoard small particles and great wines.

**Fluorescent particles** are available from several suppliers. I have generally had good luck with spheres from **BD Biosciences**, **Beckman Coulter**, **Flow Cytometry Standards Corporation** (their product line has been taken over by **Bangs Laboratories**), **Molecular Probes**, **Polysciences**, and **Spherotech**; I don't have much experience, good or bad, with beads from other suppliers. These days, practically everybody who sells beads intended for the flow cytometry market supplies reasonably complete information about their size, spectral characteristics, brightness, and uniformity, anyway; while the materials aren't cheap (p. 60), they generally perform as advertised.

I have discussed different types of particle standards on pp. 354-6, in the context of their application to quantitative immunofluorescence measurements. The process of determining whether or not a flow cytometer works begins with what are now called **Type I standards**, or **alignment particles**.

#### Alignment Particles: Fearful Asymmetry

Alignment particles are highly uniform and produce relatively strong fluorescence signals. When aligning an instrument, the routine is to run alignment particles, keeping core diameter relatively small to insure illumination uniformity, and adjust the positions of the flow cell and optical elements to maximize the fluorescence and forward scatter signals while minimizing the CV's of the distributions obtained. Data from alignment particles should be recorded on a linear scale.

When using alignment particles substantially smaller than cells (Type Ia), one should be aware that the effects of illumination inhomogeneity may be less evident with small particles than with large ones, as discussed in Chapter 4. A 2% fluorescence C.V. with 2  $\mu\text{m}$  plastic spheres can translate into a 5% C.V. in measurements of cell nuclei stained for DNA content.

A well-aligned instrument operating on a linear scale should produce **symmetric peaks** when beads or nuclei are used as standards. This is particularly important when you are making DNA content measurements. The mathematical models commonly used to deconvolute DNA histograms and calculate numbers of cells in different cell cycle phases assume that the  $G_0/G_1$  peak is symmetric. If the instrument is misaligned, and the bead peak is skewed with a tail to the right, it's a safe bet that the  $G_0/G_1$  peak will be, also; the model will conclude that the cells in the tail are in S phase. In fact, if you run the model on the bead histogram, you'll be told there are S phase beads. Don't do the DNA analysis until you fix the alignment; if you've already collected the data, don't bother with the model, which will give worthless results.

Alignment particles provide the best measure of instrument performance in terms of **precision**, as was discussed on pp. 214-5. An instrument in good working order, running

alignment particles, should produce fluorescence distributions with CVs no higher than 3 percent.

The beads from Beckman Coulter with which I am most familiar are intended for checking precision in connection with DNA measurements; their intrinsic CV is probably in the range of 1.5%.

Polysciences makes polystyrene particles in a range of sizes (from 0.1 to 10  $\mu\text{m}$ ) and colors. They have UV-excited, blue fluorescent and green-excited orange fluorescent spheres in addition to green fluorescent spheres usable with excitation wavelengths ranging from UV to blue-green; there are also spheres which are usable at other excitation wavelengths. Polysciences also supplies spheres with reactive groups to which other materials can be coupled and will make up spheres containing dyes of your choice, for a price. The uniformity of the custom spheres may vary. However, as a general rule, Polysciences 2  $\mu\text{m}$  yellow-green fluorescent spheres are very uniform; I have observed scatter CV's as low as 1% and fluorescence CV's as low as 1.2% on well-aligned instruments. The yellow-green spheres are labeled during the polymerization process; this procedure is best undertaken using relatively hydrophobic dyes, and Polysciences uses a coumarin dye which mimics the emission spectrum of fluorescein fairly well, but which is excited better in the blue-violet (436, 441, or 457 nm) than at 488 nm.

#### Reference and Calibration Particles

For standardizing immunofluorescence measurements (pp. 354-6), it is advantageous to have spectrally matched **Reference (Type II)** and **calibration (Type III) particles** bearing either known numbers of bound molecules of fluorescein, phycoerythrin, and other antibody labels (Types IIB and IIIB particles) or known numbers of antibody binding sites (Types IIC and IIIC particles). This eliminates the effect of such factors as differences in PMT sensitivity curves and differences in emission filter bandwidths, facilitating comparison of results obtained with different instruments. However, for day-to-day assessment of instrument sensitivity (see the discussion of Q and B, pp. 221-3), it is usually more convenient to use Type IIA and IIIA particles, hard-dyed beads with fluorescence characteristics that are not environmentally sensitive and also are not closely spectrally matched to the probes used for immunofluorescence measurement. It is desirable for the set of particles to include a **Type 0 standard**, or **certified blank**. If you could resolve five bead peaks in the set last week, and can only resolve three this week (see Figure 4-61, p. 222), something's wrong.

Beads labeled with known numbers of MESF of fluorescein, phycoerythrin, and other labels, phycobiliproteins, and tandem conjugates are labeled in the aqueous phase; the fluorescent label is predominantly confined to the particle surfaces, and the fluorescence CVs of these particles are typically higher than those of hard-dyed beads. The hard dyed beads used as Type IIA standards, and those in Type IIIA bead sets, tend to have somewhat higher fluorescence CVs than do alignment particles; you should therefore avoid the

temptation to use these beads for anything other than a first cut at instrument alignment. If you yield to temptation, be sure to use the brighter beads, which have lower CVs than the dimmer ones.

### Compensation Standards

When you are doing multicolor immunofluorescence analysis, the actual signal intensities you get from different detectors will be a function of how efficiently the dyes you use are excited at your excitation wavelength(s) and of the spectral responses of your detectors, and even a relatively simple task such as determining fluorescence compensation settings to separate fluorescein and phycoerythrin immunofluorescence gets hard to do unless your particles are labeled with fluorescein and phycoerythrin rather than simply fluorescing green and yellow-orange. It is possible, in principle, to use beads labeled with spectrally matched mixtures of dyes other than the labels used to compensate for fluorescence overlap, but the manufacturers of those beads will have to make their cases for such products. However, when measuring fluorescence in more than three spectral bands, it is now common to use single-label and “every-label-but-one” cell samples to determine compensation settings.

### Cells and Nuclei as Alignment Particles

I like to use **stained nuclei** for determination of both precision and linearity (p. 217), particularly in channels used for DNA content measurements. DAPI- or Hoechst dye-stained nuclei provide UV-excited fluorescence which is nominally blue, but which extends to almost 600 nm. Propidium iodide-stained cells, excited by light at wavelengths ranging from UV to yellow, emit red-orange fluorescence. If you are trying to measure DNA, you obviously want to use nuclei stained the same way you stain your samples. Peripheral lymphocyte nuclei usually have very low CV's; you can also use cell lines, but be aware that they can develop aneuploidy, which gradually increases CV's. I had that problem with CCRF-CEM cells; the ones I used originally had  $G_0/G_1$  peak CV's below 1%, but they drifted up to just under 3% after a long time in culture.

When you're trying to measure precision in a fluorescence channel in which you use red excitation, whether or not you're doing DNA measurements, your best bet may be nuclei stained with DRAQ5 or with another red-excitable dye, e.g., TO-PRO-3, oxazine 750 or rhodamine 800. If you use a dual-beam instrument with 488 nm and red beams, DRAQ5 is advantageous, because, since the dye is excited by both 488 nm light and red light, you can use the same cells to align fluorescence detectors that look at two beams. You can play the same game in an instrument with UV and 488 nm beams using ethidium or propidium as the DNA stain, since both the UV and the 488 nm beam will excite these dyes. Figure 10-1 illustrates the principle.

Since the nuclei are stained with only one dye, all of the data points in the two-parameter dot plots of Figure 10-1

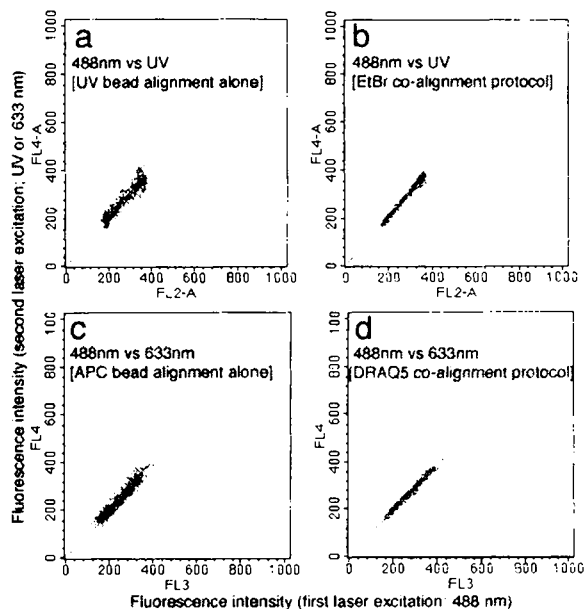

Figure 10-1. DNA histograms of ethidium- and DRAQ5-stained nuclei after alignment with beads alone (panels a and c) and after alignment using the nuclei as calibration particles (panels b and d). Courtesy of Paul Smith (University of Wales).

should, ideally, lie on a line. The plots in panels b and d in the figure are closer to this ideal than the plots in panels a and c, indicating that using the nuclei as alignment particles instead of beads results in better measurement precision.

**Chicken** and **rainbow trout erythrocytes** can serve as alignment particles; they are more commonly used as standards for DNA content estimation<sup>24</sup>. Procurement of trout cells can provide one of the many enjoyable experiences beside flowing streams that enrich the lives of flow cytometer users, at least those interested in DNA measurements.

**Glutaraldehyde-fixed chicken erythrocytes** have been popular with immunologists, because, without benefit of any staining at all, they fluoresce at about the level of brightness of cells stained with fluorescent antibodies, at least when measured in channels intended for measurement of fluorescein or phycoerythrin. Immunologists don't seem to use trout cells; I guess they only go fishing for complement.

**Riese** supplies fixed chicken and trout cells; **Orvis** ([www.orvis.com](http://www.orvis.com)) provides equipment for getting fresh trout cells. If you're after fresh chicken blood, and you live in a metropolitan area of any reasonable size, you can probably find a source of fresh-killed poultry; the old traditions held by many ethnic and religious minorities die hard.

### Rose Colored Glasses: Optical Filter Selection

It helps to calibrate flow cytometers using particles labeled with the dyes you're going to use to stain cells. It's essential to make sure you fit your detectors (and, if you use arc lamps, your excitation path) with optical filters that

transmit the wavelengths you want to measure and exclude the wavelengths you don't. Joe Trotter wrote a neat Web-based program that shows you how much light you will collect from a number of probes using various filters. You can find it online at (<http://facs.scripps.edu/spectra>).

These days, both the cytometer manufacturers and the filter manufacturers are well-informed about what is required of filters for flow cytometry, and they can generally tell you what you need for any particular probe combination and excitation wavelength(s). Most instruments use round interference filters, which are preferable to square ones because they are better sealed and therefore take longer to delaminate.

Filters do have a finite lifetime, and you should check your interference filters from time to time for evidence of delamination (pp. 153-4). Once the layers start to separate, you can generally see a pattern similar to that produced by light reflecting off oily water. It is then time to get a new filter. Although filters tend to delaminate after several years, they can die suddenly when dropped, even if the glass doesn't break, so be alert. It is also a good idea to check filter transmission, especially if you're having problems collecting enough light; this is easy to do if you have access to a spectrophotometer<sup>882</sup>.

In some cases, you'll get too much light into a detector, particularly a forward scatter detector. This is curable with neutral density (N.D.) filters. If the N.D. filters in question are going to get into or near laser beams of any appreciable power, they should be the reflective type. Reflective N.D. filters are partially "silvered" (i.e., partially coated) mirrors that transmit some light reaching them and reflect the rest. Several companies (see Chapter 11) offer reflective filters in a wide range of optical densities at reasonable prices. For lower light level applications, it's generally fine to use absorptive N.D. filters; your local camera store probably carries Kodak's line of such products.

Be careful when using a filter not explicitly intended for the purpose as a **dichroic**. Most interference filters contain some absorptive components, which fluoresce, to decrease transmission outside the passband; good dichroics dispense with these, leaving that job to the detector filters. You also can't be sure what transmission (or reflection) of a filter is like at 45° unless you measure it. Newer instruments, such as BD Biosciences LSR, LSR II, and FACSAria, use dichroics designed to work at angles of incidence other than 45°; you'll need to consult the instrument manufacturer should you want to specify a dichroic for one of those instruments, and you may have to pay one of the filter manufacturers a substantial amount to custom-make the part.

### Experimental Controls

What you will need in the way of experimental controls will vary depending on what you are trying to measure. If you suspect that somebody has run a cyanine dye, acridine orange, or another similarly sociopathic reagent through the instrument and not cleaned it afterwards, be sure to run

some unstained cells before you start with stained samples; if the unstained cells start to fluoresce after they have been running for a while, the cytometer needs a cleaning. If you've already started running stained cells, and their fluorescence starts to increase, it's too late to retrieve the data.

If you're using familiar antibodies and familiar cells, e.g., for doing T cell subset analysis, you can probably dispense with isotype controls, but you should have some controls which, in the aggregate, contain all the cell types you are looking for, just to make sure they turn up where you expect them to in the measurement space. And it's a good idea to have either cells or antibody binding beads that will give you fluorescence signals near the upper end of your range, both for setting compensation and to make sure everything will stay on scale.

When you're exploring unfamiliar territory, you'll probably be better off starting off with too many controls than with too few.

### Shake Well Before Using: When Controls Won't Help

Figure 10-2 provides an example of anomalous flow data that may perplex you in private and/or lead you to conclude in public that you have discovered some new biological phenomenon. The latter consequence is apt to be more embarrassing than the former.

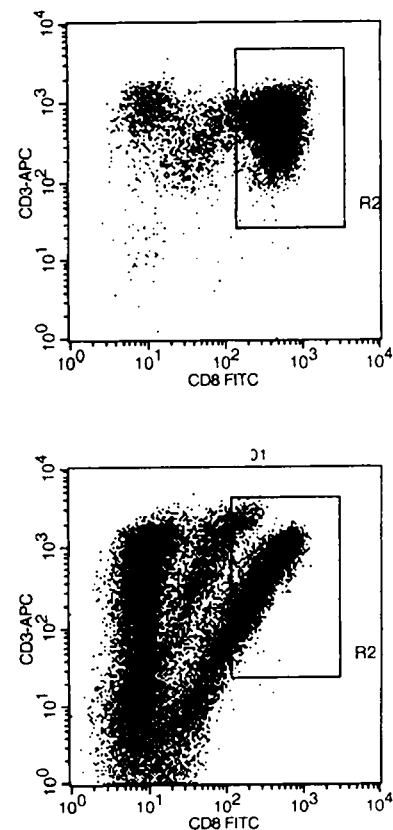

Figure 10-2. "Equal opportunity" (top panel) and "unequal opportunity" staining of T-cells (from Jörn Schmitz, Harvard Medical School)

The cells shown in Figure 10-2 were stained with the same antibodies; somebody forgot to mix the cells shown in the bottom panel, producing “unequal opportunity” staining instead of the desired “equal opportunity” staining illustrated in the top panel. It is relatively easy to identify this problem when the person preparing the cells is grossly negligent, and all or almost all of the samples, including the controls, yield results that resemble the bottom panel. The surviving lab personnel are apt to be more careful, and the occasional unmixed or incompletely mixed sample will therefore have more of an aura of mystery about it. Once you’ve seen the pattern, though, it’s easy to recognize.

## 10.2 SIGNIFICANT EVENTS IN THE LIVES OF CELLS

### Taking the Census: Cell Counting

Cell counting, discussed at length on pp. 18-21, is one of the most basic tasks in cytometry. Counting cells in a hemocytometer by visual observation is tedious and, unless one is willing to spend a long time on each sample, imprecise. The simple optical and electronic flow cytometers that became available for cell counting in the 1950’s were widely adopted in both clinical and research laboratories, eventually giving rise to modern hematology counters. As was noted in the earlier discussion, these instruments feature volumetric sample delivery, allowing absolute cell counts to be derived from the number of cells counted per unit time.

Kamentsky’s original Cytofluorograf incorporated a calibrated glass tube with photosensors at two levels in its pressure-fed sample delivery system, to detect the movement of the air-fluid interface, providing a measure of fluid flow per unit time. Fluid-level sensing volume measurement add-ons for flow cytometers have been developed<sup>1538</sup>; **Cytek** sells one such device. It is also relatively easy to adapt most instruments to receive samples from syringe pumps, which are readily available. However, most fluorescence flow cytometers do not use volumetric pumps or other calibrated means to introduce samples; absolute counts, when needed, are obtained by introducing beads into samples at known concentrations, and deriving cell counts from the ratio of the number of cells counted per unit time to the number of beads counted per unit time. The use of counting beads has facilitated performance of such clinical assays as CD4+ T cell counts using only fluorescence flow cytometers.

A recent study by Bergeron et al<sup>2917</sup> documents the sample delivery characteristics of several benchtop flow cytometers over a period of months. Sample flow rates, determined using counting beads, were relatively constant (CVs 5-7 percent). If you can accept this level of precision in cell counting for one or more of your applications, you can run counting beads at the beginning and end of sample runs to calculate the sample flow rate and check on its variation over time, and use the calculated rate to derive absolute cell counts for your experimental samples. Since you won’t need to add counting beads to each sample, you’ll save money; the beads aren’t cheap.

### A Counting Alternative: Image Analysis

It has probably not escaped your notice that digital cameras incorporating 2- and 3-megapixel CCD chips can be had for a few hundred dollars. That means the manufacturers are paying well under a hundred bucks for them. Such devices are beginning to be incorporated into a new generation of inexpensive image analysis systems.

A Danish company, **ChemoMetec**, recently introduced the **NucleoCounter**, a cell counter is built around a miniaturized low-power (1×) transmitted light fluorescence microscope illuminated by 8 green LEDs. There are no moving parts in the optical system (i.e., no focus adjustment), because the lens N.A. is low. The device uses a disposable cartridge containing propidium iodide; for a total count, cells are diluted with a permeabilizing solution and introduced into the cartridge, while, for a “nonviable” count, cells are introduced without prior permeabilization. The cartridge has a viewing area a few millimeters square, which contains a volume of 1.5 to 2 microliters; this is imaged onto a CCD through a red bandpass filter. Because the observed sample volume is relatively large, counts are more precise than would be obtained from a hemocytometer. The NucleoCounter takes about 30 seconds to do a count; it incorporates a USB connection to transfer output and images to a computer, but the device, which weighs 3 kg and measures 38 × 26 × 22 cm (W × H × D), is normally run as a self-contained system.

**Beckman Coulter** offers the **Vi-CELL™** viable cell counter, which uses image analysis to identify and count trypan blue-stained (“nonviable”) and unstained (“viable”) cells flowing through an observation chamber. This is also a relatively small, self-contained benchtop system.

A prototype image analyzing system, the **EasyCount**, which, like the NucleoCounter, incorporates a low-power, LED-illuminated fluorescence microscope, will be discussed in the section on CD4+ T cell counting.

### The Doubled Helix: Reproduction

#### The Cell Cycle and Cell Growth

It is now possible, by using flow cytometric analysis of **DNA content**, **RNA content**, **cell size**, **cell cycle-related antigens**, **BrUdR incorporation**, and the fluorescence of **tracking dyes**, to define cells’ position in the cell cycle with a precision previously unimaginable and, using cell sorting, to separate populations in different cell cycle phases for biochemical analysis or for studies in culture.

#### DNA Content Analysis

The determination of DNA content of cells or nuclei, previously discussed on pp. 21-6, 43-4, 96-7, and 301-17, is a common and widely used procedure in flow cytometry. In research laboratories, DNA content analyses are used to monitor the growth of eukaryotic and prokaryotic cells, and to detect perturbation of cellular growth patterns due to

physical, chemical, and biological agents. In clinical applications, DNA content analyses are used to refine the diagnosis and estimate the probable biologic behavior of tumors and to monitor therapy.

Since the stains used for DNA content determination bind stoichiometrically, and produce very bright cellular fluorescence, it has, to some extent, been taken for granted that, as long as the instrument used is maintaining reasonable linearity and precision, DNA analysis will be simple and straightforward. This is true enough, provided cells are well prepared and well preserved, and these steps are not always simple and straightforward.

Nuclear isolation and staining and storage reagents and procedures, using various dyes, have been described by Vindelev et al.<sup>222-5</sup>, Taylor<sup>226</sup>, and Thornthwaite et al.<sup>261,889</sup>, among others; some of these have been discussed on p. 307. While these workers and others have expended some effort in trying to devise procedures suitable for application to a wide variety of tissues and tumors, it has been my experience that preparative and staining procedures have to be modified and optimized to suit the samples at hand. Clausen<sup>613</sup>, for example, has provided an enlightening discussion of DNA analysis in keratinocytes. When analyzing DNA in solid tissues and tumors, some consideration must be given to sampling techniques; Greenebaum et al.<sup>890</sup>, for example, reported that needle aspiration gives better yields of abnormal cells than does standard excisional biopsy.

The development in 1983 by Hedley et al.<sup>610,891</sup> of a technique for **DNA analysis of nuclei from paraffin-embedded material** represented a great advance in the application of DNA analysis to tumor pathology, since it made it possible to establish correlations between DNA aneuploidy and the biologic behavior of tumors by retrospective<sup>892</sup> as well as by prospective studies. The basic method involves deparaffinization in xylene or Histoclear and progressive rehydration in ethanol solutions, followed by acid pepsin treatment for nuclear isolation. The procedure works well on material originally fixed in formalin or a formaldehyde-acetone-acetic acid mixture; results have been poor with tissue fixed in Bouin's solution and unsatisfactory when mercury-based fixatives were used.

The thickness of sections taken from the paraffin block for processing will obviously have some effect on the proportion of nuclei which can be recovered intact. Although there has been some debate on the issue<sup>747</sup>, it is reported<sup>746</sup> that 50  $\mu\text{m}$  sections produce considerably less debris, and thus better histograms, than 30  $\mu\text{m}$  or thinner sections. Hedley et al originally used DAPI as a stain, and reported<sup>891</sup> that, despite the DNA specificity of the stain, RNase treatment improved precision. While, in my own limited experience with deparaffinized material, I have gotten much better results with DAPI than with propidium, I know other people who have obtained excellent precision using propidium.

## Mathematical Models for DNA Analysis

**Calculation of population fractions in different cell cycle phases** has undoubtedly generated much too much debate over the years among people who do flow cytometric DNA analysis. When DNA content determination is based on a single parameter measurement, there will be artifacts and interferences to be dealt with under the best of circumstances, i.e., when the samples consists of freshly prepared cells from a population grown in suspension culture. Under less ideal circumstances, as in analysis of material from solid tumors, there may be no legitimate conceptual model for dealing with the complexity of the sample.

If the flow cytometer is linear, it can be expected that a population exhibiting a DNA diploid peak at channel  $n$  will have a DNA tetraploid peak at channel  $2n$ ; however, minor nonlinearities (a few channels worth) are not uncommon in the flow cytometers used in the real world, and a noticeable fraction of older systems exhibited marked nonlinearity. A continuum of **debris** is frequently superimposed on at least the lower channels of a DNA histogram. **Doublets** due to **clumps** and/or **coincidences**, resulting from physical attachment or proximity of cells, may register as DNA tetraploid cells unless a two-parameter measurement scheme is used, in which a plot of pulse peak height vs. area (integral) or a plot of fluorescence vs. a pulse width measurement is used to permit discrimination between the doublets and the DNA tetraploid cells. Newer mathematical models<sup>1184-5,1307-8</sup> can deal with both debris and doublets.

Once one gets the debris and doublets out of the way, it becomes relatively easy to deal with a distribution which contains a single  $G_0/G_1$  peak, an S phase distribution, and a  $G_2+M$  peak, and not too much harder to handle a highly DNA aneuploid distribution with proliferating cells and an isolated peak of normal DNA diploid stromal cells in  $G_0/G_1$ . Jerry Fried, who was one of the first people to do mathematical modeling of DNA histograms, opined to me years ago that, if you had a clean (little debris, few doublets) distribution with a CV of less than 3 percent, you might as well estimate cell cycle phases by eye. On the other hand, if you have overlapping DNA diploid and DNA aneuploid distributions, each with a visible  $G_0/G_1$  and  $G_2+M$  peak, it's difficult for a model to decide which part of the S-phase belongs to which population, unless there are discernible jumps in that region.

Mathematical models for deconvoluting DNA histograms were originally intended principally for application to analysis of the perturbation of cell cycle kinetics by therapeutic agents, and they worked fine when applied to clean systems. What happened when people first started trying to use DNA analysis for clinical purposes was that they went running to mathematical models when they came up with distributions with CV's of 8 percent, or 12 percent, in the hope that the truth would come out of hiding if given enough computer time. This made precious little sense;

Shapiro's Seventh Law reminds us that bad data won't get better.

Generally speaking, the critical information sought from mathematical models, particularly by clinicians applying the models to distributions from tumor samples, is what is variously known as the **proliferative fraction**, **percentage of cells in S phase**, or **S-phase fraction (SPF)**, because this, like DNA aneuploidy, may be predictive of tumors' biologic behavior. To be sure, eyeball estimation and several different mathematical models may give several different numbers for SPF in a given sample<sup>893,5</sup>.

In a previous edition, I said that it struck me as extremely unlikely that one method of SPF would turn out to yield a predictor of biologic behavior that was statistically significantly better than others. I **was wrong!** I didn't consider the effects of debris on SPF calculations. Kallioniemi et al.<sup>742</sup> used a background subtraction algorithm to compensate for the effects of slicing of tumor cell nuclei during preparation of paraffin-embedded specimens, and analyzed DNA histograms from breast and prostatic carcinomas. Median SPF's corrected for nuclear slicing were lower than uncorrected ones in both breast cancer (7.6% vs. 5.7%) and prostate cancer (6.7% vs. 4.2%). Corrected SPF levels resulted in a more significant survival difference between breast cancer patients with values above and below the median ( $p = 0.0014$  vs.  $p = 0.014$ ) and in a higher relative risk of death (4.5 vs. 3.1). The same was true for prostate cancer survival ( $p$  less than 0.0001 vs.  $p = 0.002$ ) and relative risk of death (5.3 vs. 3.1). Also see pp. 25-6.

The two programs most widely used for DNA histogram analysis are Bruce Bagwell's **ModFit™** (Verity Software House) and Peter Rabinovitch's **Multicycle™** (Phoenix Flow Systems); both use modeling to minimize effects of clumps and debris. An example of the application of ModFit to deconvolution of a DNA histogram with DNA diploid and DNA aneuploid components is illustrated in Figure 1-10 (p. 25); the use of the same program, in a modified form, in studies with tracking dyes is shown in Figures 7-23 and 7-24 (pp. 372-3).

If you are hoping to get good data from a deconvolution program, you'll need a lot of cells in the sample<sup>390</sup>, perhaps as many as 200 cells per channel in S-phase (p. 240). That can mean 50,000 or more cells overall, even if you work with a 256-channel DNA histogram.

### Clinical Application of DNA Content Analysis

As was noted on pp. 25-26, the quality of analysis of both ploidy and S-phase fraction has an impact on the prognostic relevance, or lack thereof, of the resultant data.

It has been reported<sup>896</sup> that **gating on forward and orthogonal scatter** may be useful in locating DNA aneuploid nuclei, since these parameters may differentiate tumor and stromal cell nuclei. It is also possible to stain tumor cell populations with fluorescent antibodies, e.g., anti-cytokeratin, which define tumor or stromal cell populations, and to use fluorescence gating<sup>1743,4</sup> to select the tumor cells

for analysis. This facilitates detection of small subpopulations of DNA aneuploid nuclei in specimens.

In the mid-1980's, when it looked as if flow cytometry was going to go bounding into the clinical laboratory whether the clinical laboratory was ready for it or not, the National Cancer Institute set up a nationwide network of five institutions, all with considerable experience in the field (Memorial Sloan-Kettering Cancer Center, New York, NY, Montefiore Medical Center, New York, NY, Rush-Presbyterian-St. Luke's Medical Center, Chicago, IL, the University of California at Davis, Davis, CA, and the University of Rochester, Rochester, NY), to do cooperative studies on flow cytometry of bladder cancer. The good news is that these five institutions, which used different stains, hardware, and software, were able to obtain comparable results in analysis of deparaffinized sections from cases of human transitional cell carcinoma of the bladder<sup>897,8</sup>. The not-so-good news, or perhaps I should call it the sobering fact, is that it was much harder to get less of a consensus from analyses of specimens that were not previously in paraffin, even with all of that expertise being brought to bear on the problem. Preparation and preservation of samples to the point at which they can be sent around the country and produce reliable results was not then a *fait accompli*, which shouldn't have surprised me.

In October, 1992, a DNA Cytometry Consensus Conference<sup>1745</sup>, bringing together 32 experts in the field from Europe and North America, was held under the auspices of the International Society of Analytical Cytology. Guidelines<sup>1746</sup> for implementation of clinical DNA cytometry, both flow and image, and consensus reviews of the role of DNA cytometry in bladder<sup>1747</sup>, breast<sup>1748</sup>, colorectal<sup>1749</sup>, and prostate<sup>1751</sup> cancer and in neoplastic hematopathology<sup>1750</sup> were developed and published in *Cytometry* (Volume 14, Number 5) in 1993.

The Conference echoed the recommendations of the Society for Analytical Cytology's Committee on DNA Nomenclature<sup>741</sup>, made in 1984, that the terms **DNA diploid** and **DNA aneuploid** be used to describe cells containing apparently normal and apparently abnormal amounts of DNA unless actual ploidy is established by cytogenetic studies, and that the degree of DNA content abnormality be given by the **DNA index (D. I.)**, which is the ratio of  $G_0/G_1$  peak locations of the sample (tumor) cells and normal or reference cells. In order for a sample to be classified as DNA aneuploid, two distinct  $G_0/G_1$  peaks must be present in the histogram.

It was stressed that the normal cell or stromal component present in tumor samples best represents DNA diploidy, and therefore provides the best standard. This is an important point because, while DNA content in normal cells from any given individual is quite uniform, sufficient polymorphism exists in the human race as a whole to account for a range of variation of about 7% in DNA content in DNA diploid cells (G. van den Engh, personal communication).

It was also recommended that details of the methods used to isolate and prepare cells and to analyze histograms be provided in publications dealing with DNA content analysis, and that mean CV's and ranges for both DNA diploid and DNA aneuploid populations be included. Samples from solid tumors should, in general, contain at least 20% tumor cells, and, particularly if SPF is to be determined, a minimum of 10,000 events should be analyzed. When S-phase populations of DNA diploid and DNA aneuploid cells overlap, a weighted average of the two SPF's should be reported; however, it has not been determined whether this practice yield prognostic information as good as or better than is obtained when all S-phase is attributed to the tumor cells.

It was further recommended that each laboratory should define its own ranges of DNA diploidy and aneuploidy, and of high, intermediate, and low SPF, for each tumor type, and that studies of outcomes be based on analyses of three or more groups (e.g., high, intermediate, and low SPF) rather than on analysis of patients falling above and below the median.

The consensus review on bladder cancer<sup>1747</sup> recommended analysis of both biopsy and bladder irrigation samples at diagnosis and of irrigation samples at follow-up; it was felt that flow cytometry should not be used either for bladder cancer screening or for work-up of microscopic hematuria.

According to the breast cancer consensus review<sup>1748</sup>, while operable lesions with a D. I. of 1.0 have a favorable prognosis compared to DNA aneuploid tumors, DNA index does not achieve independent prognostic significance because it is strongly correlated with more powerful prognostic indicators. SPF, while strongly associated with tumor grade, retains independent predictive power (but see pp. 25-6). It was recommended that fresh frozen samples containing a substantial proportion of malignant cells be used for analysis.

The colorectal cancer consensus review<sup>1749</sup> concluded that prognostic significance of DNA aneuploidy has not been established, although there is strong evidence for it in Dukes' stage B and C lesions. SPF appears to be a more powerful prognostic factor.

According to the consensus review<sup>1751</sup>, neither DNA aneuploidy nor SPF has been established as predictive in prostate cancer; few studies have been done on the latter, while studies on the former have yielded conflicting results.

In hematologic neoplasms<sup>1750</sup>, DNA aneuploidy is associated with favorable outcomes in acute lymphocytic leukemia (ALL) in children, but not in adults; there is no prognostic value for ploidy analyses in acute myelocytic leukemia (AML) or non-Hodgkin's lymphoma (NHL), but SPF is prognostically significant in NHL.

The potential for clinical application of cytometry, whether flow or image, in cancer depends on the prevalence of the disease. According to the 1993 prediction of American Cancer Society<sup>1752</sup>, there would be 1,208,000 new cancer cases in the U.S. in 1994; of these, 51,200 would represent bladder cancer, 183,000, breast cancer, 149,000, colorectal

cancer, and 200,000, prostate cancer. Among the 94,200 hematologic neoplasms, there would be 45,000 cases of NHL, 12,500 of lymphocytic leukemia, and 11,400 of granulocytic leukemia, with the leukemia statistics representing both acute and chronic forms of the disease.

### DNA Content Alternatives: Static Photometry and Scanning Laser Cytometry

**Static photometry and image analysis** can produce DNA content distributions from Feulgen-stained cells with precision almost comparable to that obtained from flow cytometry, at least when clinical specimens containing isolated nuclei are being analyzed. In theory, one can use image analysis to do DNA content determinations on nuclei in tissue, but the software remains a problem. While static methods are slower than flow cytometry, you do get to keep the cells on the slide, and to decide which are likely to be representative of tumor cells and stromal elements, and you don't need that many cells in a sample, which is advantageous when you are trying to do ploidy or SPF determinations on needle biopsy specimens.

The relatively new technique of **scanning laser cytometry** offers many of the advantages of both flow cytometry and image analysis. **CompuCyte's Laser Scanning Cytometer (LSC<sup>TM</sup>)**<sup>2047,2380-1,2918</sup> analyzes cells on a slide or other solid substrate, and produces low-resolution image data from which whole-cell measurements of DNA content, immunofluorescence, etc. can be derived. The LSC measures forward scatter and fluorescence in four or more spectral ranges using a 488 nm laser as its primary light source; most units also have a red laser and a violet diode laser is also offered as an option. The LSC is built around an upright microscope; the newer **iCyte<sup>TM</sup>**, built around an inverted microscope, offers some additional features and the capability for analysis of specimens in microtiter plates and culture dishes. Both instruments are substantially faster than the older image analysis systems, making it feasible to analyze as many as a few thousand cells in a clinical sample. Although CVs obtained using the LSC in DNA analysis are typically higher than those obtained by flow cytometry, several reports have found the LSC and flow cytometry equally effective for ploidy and SPF measurement in solid tumors<sup>2919-27</sup>. Other applications of scanning laser cytometry in general and of the LSC in particular will be discussed elsewhere in this chapter.

### The Mummy's GC/AT: DNA Content Analysis in Anthropology and Forensic Science

Cook<sup>1753</sup> reported the ability to detect intact nuclei in DAPI-stained cortical bone samples removed from individuals buried in Egypt approximately 2,000 years ago. When intact cells are found in a sample, it increases the likelihood that further investigations, such as extraction, amplification, and sequencing can be done successfully. Although the point was not specifically discussed, it seems likely that sorting intact nuclei from a sample containing large amounts of

debris would yield a better starting preparation for further analysis.

This technique may be applicable to fresher material for forensic purposes as well, even if it won't quite get us to Jurassic Park. Schoell et al<sup>2923,4</sup> presented experimental evidence that flow sorting could be used to isolate sperm from vaginal samples taken from sexual assault victims for subsequent PCR amplification and identification; there are two major problems with this work. First, while cytometry allows the identification of sperm on the basis of haploid DNA content and other characteristics, flow sorting is not well suited to work with very small numbers of cells; a slide-based technique such as **micromanipulation**<sup>2925</sup> (relatively low-tech) or **laser capture microdissection**<sup>2926-32</sup> (relatively high-tech) would be preferable, assuming the authorities have the budget. Second, the authors appear to have published the same paper twice.

Cina<sup>2933</sup> and Di Nunno<sup>2934-6</sup> and their colleagues report that the degree of degradation of DNA in various tissues, as determined by flow cytometry, can provide a precise estimate of time of death; they recommend a needle biopsy of the liver as a source of cells. Maybe I should follow in my father's footsteps and set up a forensic cytometry lab.

### Half a Genome is Better than None: Sperm Sorting

*Brave New World* aside, the separation of X- and Y-chromosome-bearing sperm is of great practical and economic importance for breeders of domestic animals<sup>2324</sup>. The obvious way in which to do this depends upon the demonstration of differences in DNA content between the two kinds of sperm. However, it is probably fair to say that earlier flow cytometric studies of sperm DNA<sup>96,121,582-4</sup> revealed as many instrumental differences between flow cytometers as DNA content differences in sperm.

The DNA in sperm heads is in a highly condensed state, and there are a variety of shapes of sperm heads, many of them asymmetric, in sperm from different animal species. This asymmetry causes artifacts in DNA content measurements in some flow cytometers in which sperm passing through the instrument in different orientations are unevenly illuminated or in which collection of fluorescence is perturbed by differences in orientation<sup>121</sup>. Slit-scanning<sup>582,2311</sup>, and fluidics that align cells passing through the apparatus<sup>583</sup>, have been used to improve measurement quality; Métézeau et al<sup>1967</sup> used a combination of axial extinction and forward scatter measurements to detect orientation, essentially compensating the DNA measurement. As Figure 7-11 (p. 311) dramatically illustrates, it is possible to build a flow cytometer optical system that can almost completely distinguish X- and Y-chromosome-bearing sperm, although whether such resolution can be achieved with preservation of viability remains in question.

It is now possible to discriminate and sort X- and Y-sperm from domestic animals<sup>584,1968-78</sup> and men<sup>1979,2322-3</sup> by flow cytometry. There was some question as to whether sperm

stained with Hoechst 33342 for viable cell sorting DNA fluorochromes were desirable for use in insemination; Libbus et al<sup>1241</sup> noted an increased frequency of chromosome aberrations when sperm which had been stained and sorted were microinjected into hamster eggs, but Morrell and Dresser<sup>1980</sup> did not find abnormalities in the offspring of rabbits fertilized with sperm which had been stained with the Hoechst dye, whether or not the sperm had been sorted. There have been live births in animals following fertilization with sorted sperm<sup>1973,1977</sup>; Johnson, Flook and Hawk<sup>1973</sup> reported 94% female offspring in rabbits using X-enriched sperm and 81% male offspring using Y-enriched sperm.

Larry Johnson, of the U.S. Department of Agriculture, is the undisputed world leader in sperm sorting; after doing extensive work with sperm from domestic animals, he and his collaborators at the Genetics and IVF Institute (Fairfax, VA)<sup>1979</sup> sorted human sperm, achieving 75% purity of Y-sperm and 82% purity of X-sperm, and suggested that sorting might be a useful way of dealing with X-linked diseases in man. A report of this work inspired one of the science writers at *The Boston Globe* to produce a column suggesting that we might eventually be able to use gene probes to preselect "nice" offspring; I expect Larry got a good laugh out of the copy I sent him. Then he and his colleagues went back to work, and in 1998 they reported deliveries of normal babies after insemination or *in vitro* fertilization with X-enriched sorted sperm. Offspring were of the desired female gender in 92.9% of the pregnancies<sup>2937-8</sup>.

I heard a rumor when I was writing the last edition that some success in isolation of X- and Y-sperm had been achieved using monoclonal antibodies raised by immunization of mice with sperm separated based upon DNA content, but I think I got a bum steer, which is just what cattle breeders are trying to avoid by separating sperm. Actually, one antibody that was thought to be preferentially expressed on Y-sperm has turned out not to be<sup>1978,2939</sup>. An attempt to separate X- and Y-sperm on a Percoll gradient also didn't work<sup>1981</sup>.

Van Munster and colleagues<sup>2541-2</sup> found that sperm volume, measured by interferometric flow cytometry, was proportional to DNA content, and succeeded in obtaining fractions of bull semen enriched for X- and Y-sperm by sorting. This will undoubtedly stimulate somebody to build a sperm sorter incorporating a Coulter volume measurement; if it works as well as the current hardware and eliminates the need for Hoechst 33342 staining, the technology is likely to be widely used to assist both human and animal reproduction.

**XY, Inc.**, established in 1996 as a joint venture between Cytomation (now DakoCytomation) and Colorado State University, runs several facilities for sorting animal sperm. They have licensed the patents based on Larry Johnson's work. Figure 10-3, on the next page, illustrates the procedure used at X-Y for separation of X- and Y-sperm from bull semen. The apparatus is a modified MoFlo cell sorter; a beveled injector needle is used to orient sperm, and Hoechst

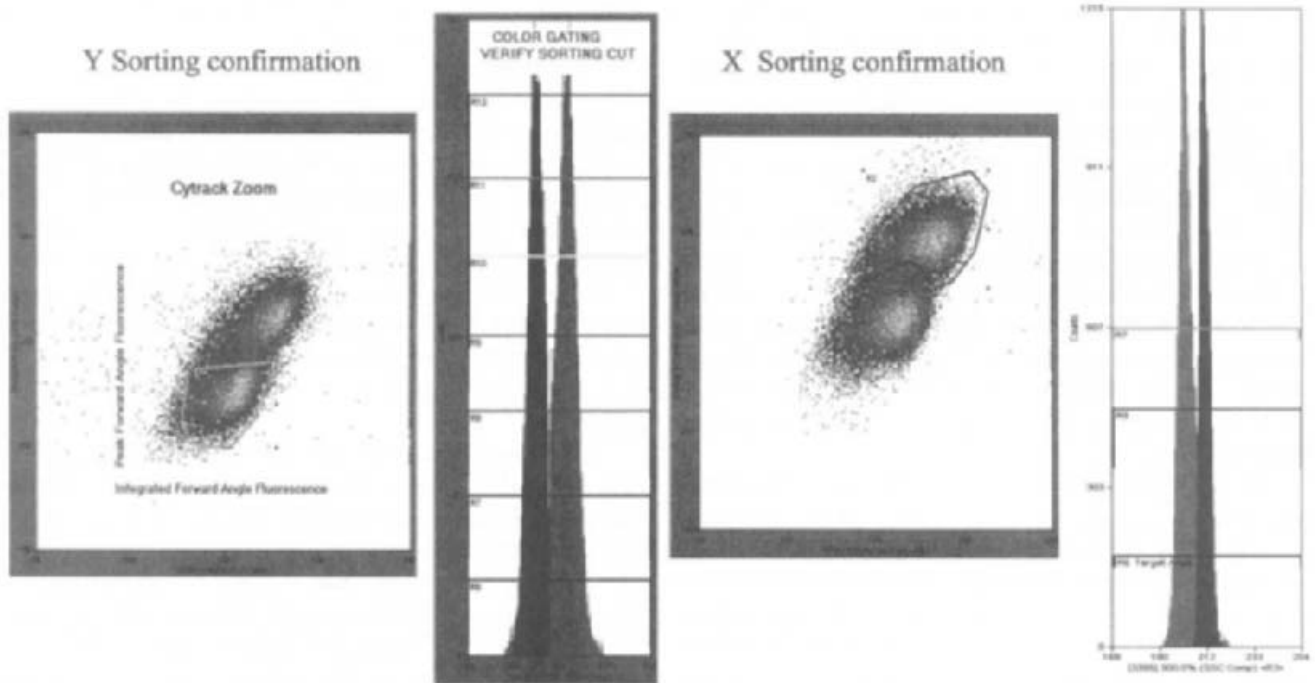

Figure 10-3. Separation of X- and Y- bull sperm based on forward and orthogonal scatter and forward and orthogonal Hoechst 33342 fluorescence measurements. Courtesy of Mike Evans, XY, Inc.

33342 fluorescence is measured in the forward direction as well as through conventional orthogonal collection optics. Properly oriented sperm are gated based on measurements of forward and side scatter and fluorescence; sort gates are set as shown on a magnified display of forward fluorescence peak vs. integral values.

### The Widening $G_0/G_1$ re Detecting Mutation

The very first issue of *Cytometry* (July 1980) contained a paper by Otto and Oldiges<sup>2941</sup> on flow cytometric detection of chromosomal aberrations (clastogenic effects) induced in cultured cells by mutagens and x-rays. The authors used a high-resolution arc-source flow cytometer to analyze isolated chromosomes and cell nuclei stained with DAPI. The detection of clastogenic effects is a mainstay of toxicologic studies, and, until Otto and Oldiges proposed a flow cytometric method, required examination of metaphase chromosomes on slides. Their initial experiments correlated clastogenic effects with increases in the CV of peaks representing the largest chromosome. They then reasoned that, because cell division in cells containing chromosomal aberrations results in unequal distribution of DNA between daughter cells (i.e., mere aneuploidy is loosed upon the world), it should be possible to detect clastogenic effects by measuring DNA content distributions of whole nuclei and determining whether the CV of the  $G_0/G_1$  peak was greater in cells exposed to clastogenic agents than in controls. The whole cell method has two obvious advantages; it eliminates the need to synchronize cells in mitosis to obtain chromosomes for

analysis, and, because nuclei contain substantially more DNA than do chromosomes, it decreases the contribution of photoelectron statistics to measurement variance.

As Otto and Oldiges put it, "This effect is assumed to be measurable, using high resolution flow cytometry..." The DNA content distributions measured from their control cells had CVs of 1.2 and 2.0 percent, making it relatively easy to detect small, dose-dependent increases in cells exposed to clastogenic agents. It can safely be assumed that the method has been used by others who, for various reasons, have not obtained equivalent measurement precision. It is therefore logical to ask whether there is a reliable statistical procedure for analysis of CV data obtained from clastogenicity experiments. Misra and Easton<sup>2942</sup> have developed one that they claim is more robust than some that have been used previously; it's worth looking into if you work in this area.

### Detecting DNA Synthesis: Cell Kinetics

#### Kinetics Before Flow Cytometry: Mitotic Indices, Doubling Times, and Radiolabel Studies

In order to precisely define the **kinetics** of a cell population (an excellent discussion of cell kinetics and the relevant radioisotope methodology can be found in Steel's book<sup>382</sup>), you really need to know both the cells' **DNA content**, and their **DNA synthesis rate**. I have given a little bit of the history of cell kinetic studies on pp. 85-6. Before 1950, it wasn't easy to measure either DNA content or synthetic rate, so the literature on kinetics was restricted to analysis of **mi-**

**otic indices and doubling times.** The **mitotic index** is obtained “simply” by counting the fraction of mitotic cells in the population, which isn’t always as easy as it sounds. Under the best of circumstances, it isn’t always easy to identify cells in early prophase and late telophase; in mixed cell populations, e.g., in bone marrow or tissues, you can’t always be sure which of the cells you’re looking at belong to the subpopulation of interest. Also, as I found out many years ago, unless you analyze, fix, or refrigerate samples within minutes after they are taken, you may get erroneously low mitotic indices; at least some mitotic cells in excised tissue at room temperature will proceed happily through mitosis. Finally, if the mitotic index is low, you have to count a lot of cells to get a precise value. Cytometry can help with that; see pp. 277, 320 and 462.

**Doubling times** for nonmotile cells can be determined unequivocally using the venerable method of **time-lapse photography**<sup>2943-4</sup>, which allows an observer to monitor the development of clones from single cells. These days, it makes more sense to use a more sophisticated technique such as **laser scanning cytometry**, which allows multiparameter measurements to be done on each cell in a clone<sup>2945</sup>. Doubling times for cells in suspension can be estimated fairly reliably from visual or instrumental cell counts done at intervals. However, when we get back to the real world, we can’t derive equally trustworthy information from such data as tumor volume measurements, because **cell loss** is at least as important as the kinetics of reproductively competent cells in determining tumor growth rates. Cell loss should be detectable in time-lapse studies of individual cells and their progeny, but may or may not be detectable in cell suspensions.

The introduction of **tritiated thymidine (<sup>3</sup>H-TdR)** as a tracer in the late 1950’s made it possible to estimate DNA synthesis rates in populations by bulk measurements of uptake, done in scintillation counters, and to determine heterogeneity in labeling patterns by **autoradiography**. Several assumptions underlie the use of <sup>3</sup>H-TdR for the study of DNA synthesis patterns in cell populations. It is assumed that the <sup>3</sup>H-TdR is either incorporated into DNA by cells or lost, i.e., that the tritium label is not transferred to cellular constituents other than DNA as a result of thymidine catabolism. It is also assumed that cells do not have large endogenous thymidine pools, and will thus incorporate exogenous <sup>3</sup>H-TdR into DNA if the labeled material is present during the period of DNA synthesis. This issue can be forced to some extent by adding a substance such as 5-fluorouracil during the period of <sup>3</sup>H-TdR exposure. It is assumed that the administered label is equally accessible to all cells in the population under study. Finally, it is assumed that the tritium label is not administered a heavy enough dose of radiation therapy to the cells to perturb their DNA synthesis. These same assumptions must be made when another labeled nucleotide, e.g., bromodeoxyuridine (BrdU, BrdUrd, etc.), is used in place of as <sup>3</sup>H-TdR as a DNA label, and it can sometimes be shown that one or more

assumptions are invalid, depending upon the cell system chosen, the dose of tracer used, etc.

When incubated with <sup>3</sup>H-TdR, either for a brief period (a **pulse** of 5-60 minutes’ duration) or for a longer time, cells synthesizing DNA, i.e., those in the S phase of the cell cycle, incorporate the tracer. The **labeling index (L.I.)**, i.e., the fraction of cells incorporating enough <sup>3</sup>H-TdR during incubation to produce exposed grains in an overlying autoradiographic emulsion, provides information about DNA synthesis patterns in a cell population. After pulse labeling, the L.I. should represent the percentage of cells in S phase; if there are no quiescent cells in the population, the L.I. should approach 100 percent as the labeling time increases.

Analysis of a cohort of cells labeled at a specific point in the cycle should provide an estimate of the average **generation or cell cycle time**, provided this does not exhibit tremendous cell-to-cell variance. The most common technique for deriving such information follows the **percentage of labeled mitoses (PLM)** over time following pulse labeling. The resulting **PLM curve** is a periodic function, with the time interval between the first and second relative maxima representing the generation time.

While some attempts were made to mechanize autoradiographic grain counting, the vast majority of studies involving quantitative autoradiography were done by human observers counting grains under transmitted light microscopes. This process was tedious, but the manpower and the microscopes were readily available at the time, whereas measurements of DNA content by Feulgen staining or UV absorption would have required microspectrophotometers, which were hard to come by. The few studies that combined Feulgen DNA content measurements and autoradiography took months to do.

### Labeling Index versus DNA Content

Since the early 1970’s, flow cytometers have provided us with cheap and plentiful DNA content analyses, while autoradiography has not gotten appreciably easier, despite the introduction of high specific activity tritiated thymidine and of other technical refinements that shorten exposure time from months to hours. As might be expected, this has led many people to employ flow cytometry almost to the exclusion of autoradiography in studies of cell kinetics. The distribution of **DNA content** in cell populations, like the labeling index, provides an estimate of the fraction of cells in S phase; in this case, the estimate is obtained from the fraction of cells with a measured DNA content between that of the  $G_0/G_1$  (diploid or 2C) and  $G_2 + M$  (tetraploid or 4C) values (for the population in question; in tumor cells, the 2C value frequently differs from the 2C value for normal cells of the host).

Several circumstances can produce discordance between the S phase fractions estimated from labeling indices and from DNA content measurements. In principle, DNA repair on a massive scale might produce labeling indices higher

than the fraction of cells with S phase DNA content, but the discrepancy, when one exists, is usually in the other direction. An "S<sub>0</sub>" population of cells, which have stopped synthesizing DNA in the middle of S phase, will be characterized as in S phase by their DNA content but will not label with <sup>3</sup>H-TdR; the fraction of cells in S phase will therefore be higher than the labeling index.

The same result will occur if the cells being studied catabolize thymidine. Squirrel cells do this<sup>831-2</sup>; when looking at cell kinetics in hibernating ground squirrels<sup>833</sup>, I found no labeling with thymidine in marrow cells from hibernating animals – and none in cells from animals that weren't hibernating, either. Using tritiated deoxycytidine, which squirrels don't catabolize, as a tracer, it was possible to demonstrate a greater than 10-fold decrease in DNA labeling during hibernation, although DNA histograms from hibernating and alert animals showed the same percentages of cells in S phase. This certainly convinced me that critical studies of cell kinetics require measurement of both DNA content and labeling; but it's easy to say things like that when you're not stuck with doing all the work.

### Early Flow Cytometric Approaches to Labeling Using BrUdR and <sup>3</sup>H-TdR

A strategy proposed by Latt<sup>236-8,383-4</sup> (also see p. 308) was based on the observation that the fluorescence of dyes such as Hoechst 33258 and 33342 was partially quenched when the dyes bound to regions of DNA in which **bromodeoxyuridine (BrUdR)** was incorporated in place of thymidine. Latt, George and Gray<sup>384</sup> showed that Hoechst dye fluorescence in cells grown in the presence of BrUdR was decreased relative to the fluorescence of cells grown without BrUdR. Under these circumstances, however, Hoechst dyes can provide information about DNA content or information about BrUdR incorporation, but not both.

Other techniques for estimation of DNA synthesis rates based upon BrUdR effects on the fluorescence of a DNA fluorochrome were described by Swartzendruber<sup>385</sup> and by Darzynkiewicz et al<sup>386</sup>. Swartzendruber found that mithramycin fluorescence was enhanced in cells exposed to BrUdR, while Darzynkiewicz et al reported that the green DNA-specific fluorescence of AO was decreased approximately 40% in stimulated lymphocytes grown for a generation time in the presence of BrUdR. Maddox, Johnson, and Keating<sup>1654</sup> reported in 1989 that AO quenching could be used in a relatively routine fashion for detection of BrUdR incorporation in normal and leukemic marrow cells.

Gray et al<sup>387</sup> combined flow cytometry and isotope techniques to devise a rapid method analogous to the classical radioisotope technique of determining the **fraction of labeled mitoses** in a cell sample. Cells pulse labeled with tritiated thymidine (or another radioactive DNA precursor) are harvested at different times and stained with a DNA fluorochrome, after which cells within a narrow window in mid-S phase (defined as "S<sub>m</sub>") are sorted and the radioactivity per cell (RCS) determined by scintillation counting. The dura-

tion of S phase and of the total cell cycle are determined from fluctuations in RCS<sub>i</sub> values with time.

### Detection of Incorporated BrUdR with Hoechst Dyes and Propidium Iodide

Bohmer and Ellwart<sup>388-9</sup> and Noguchi et al<sup>390</sup> independently described essentially identical methods that estimated both BrUdR incorporation and total DNA content by combining ethidium or propidium with the Hoechst dyes for nuclear staining. Both dyes are excited by UV light; however, since Hoechst dye fluorescence is quenched by BrUdR and ethidium and propidium fluorescence are not, cells that have labeled will have relatively lower Hoechst dye fluorescence than unlabeled cells. By analysis of the Hoechst dye fluorescence distribution of cells with propidium fluorescence values corresponding to a window in S phase, it is possible to get the same information as would be obtained from cell sorting and scintillation counting in the RCS<sub>i</sub> method<sup>387</sup>, with less expenditure of time and effort.

Proponents of the method<sup>1655-6</sup> reported that flow cytometric analysis of BrUdR-quenched 33258 Hoechst fluorescence could be used to measure the G<sub>1</sub>, S, and G<sub>2</sub> + M phases in each of three successive cell cycles after mitogen stimulation of peripheral blood lymphocytes. The data allow assessment of growth fraction, lag-time, compartment exit rate, compartment duration, and compartment arrest. Asynchronous cell populations can be analyzed as well<sup>1657</sup>, and low-power He-Cd lasers are usable as UV excitation sources<sup>1658-9</sup>.

### Detection of BrUdR Incorporation with Anti-BrUdR Antibodies

Gratzner et al<sup>391-2</sup> proposed the use of fluorescent antibodies to detect BrUdR incorporation in the mid 1970's, at which time problems in the development and standardization of antisera limited application of the technique. Improved antisera<sup>393</sup> and, later, development of a monoclonal antibody to BrUdR<sup>394</sup> (available from B-D) increased sensitivity and specificity sufficiently to make immunofluorescence a practical and widely used method for estimation of DNA synthesis from BrUdR incorporation; it is possible to detect a much smaller amount of BrUdR with antibody than could reliably be detected by the quenching technique described above. The entire November 1985 issue of *Cytometry* was devoted to the development and use of monoclonal antibodies against BrUdR; this has also appeared in book form<sup>334</sup> and is an essential reference on the technique.

If you can use the anti-BrUdR antibody method, you can probably distinguish cells in early S phase from those in G<sub>1</sub> and cells in late S phase from those in G<sub>2</sub> well enough so you won't need to do elaborate mathematical analyses to deconvolute DNA histograms. The flow cytometric aspects of the procedure are straightforward, since the reagents used, normally propidium iodide and fluorescein-labeled antibodies, can be excited by a single blue-green beam, making the technique usable on most instruments.

Whether or not you can readily apply the anti-BrUdR immunofluorescence technique to the cell type(s) you want to study is another matter. The sample preparation methodology described by Dolbeare et al<sup>195,835</sup> is technically demanding, must be optimized for individual cell types, and works well with some cell types and not with others. Thus, although measurements of labeling indices may provide important information relevant to the prognosis and/or treatment of tumors, the immunofluorescence method for making such measurements, at its present state of development, is not readily adaptable to routine clinical use.

Difficulties in cell preparation arise because the "anti-BrUdR" antibody reacts only with BrUdR in single-stranded DNA; therefore, before the antibody can be used, nuclear DNA must be denatured *in situ* by treatment with acid and/or by heating<sup>836-8</sup>. In some cases, it is essentially impossible to get enough denaturation to bind antibody while leaving enough DNA to stain; anti-BrUdR antibodies cannot be used, for example, to analyze DNA synthesis in bacteria. A high-affinity monoclonal antibody to **iododeoxyuridine** in DNA has also been made<sup>839</sup>; this can offer increased sensitivity compared to anti-BrUdR antibodies, but still requires DNA denaturation before it can be used. According to Hoy, Seamer, and Schimke<sup>160</sup>, the cell density, volume of solution used, and pH at which denaturation is carried out are all critical. Larsen et al<sup>161</sup> reported that DNA analysis was better, and that there was less cell aggregation and cell loss, when the wash steps were omitted following immunofluorescent staining. Still and all, it's not easy.

When technical considerations do permit its application, the anti-BrUdR antibody technique can be used with pulse and continuous labeling to estimate all cell cycle parameters that could be estimated from <sup>3</sup>H-TdR incorporation<sup>840-3</sup>. Bakker et al<sup>162,3</sup> extended the methodology to permit double-labeling experiments to be done with chloro- and iododeoxyuridine and two different antibodies; Toba, Winton, and Bray<sup>164</sup> reported that BrUdR incorporation and phenotype could be measured simultaneously, using fluorescein- and phycoerythrin-labeled antibodies, respectively, if 7-AAD instead of propidium were used to stain DNA. White and his colleagues<sup>1193,1605</sup> and others (see p. 247 and references 2492-6) have developed models for bivariate analysis of BrUdR incorporation data.

### Cytochemical Detection of BrUdR Incorporation Using Difference and Ratio Signals

Crissman and Steinkamp<sup>64</sup> described a rapid cytochemical method for detecting BrUdR that does not use antibodies and does not require DNA denaturation; however, it calls for fancier hardware, once again dashing our hopes for a free lunch.

The quenching of Hoechst dye fluorescence by BrUdR serves as the basis for the new technique, as it does for the Hoechst/PI method described previously. In this instance, following culture in the presence of BrUdR, cells are fixed (in cold ethanol) and stained simultaneously for 1 hour with

0.5 µg/ml Hoechst 33342 and 5 µg/ml mithramycin in the presence of 5 mM MgCl<sub>2</sub>. They are then analyzed in a dual-beam flow cytometer, using UV light to excite Hoechst dye fluorescence and violet or blue-violet light to excite mithramycin fluorescence.

In Crissman and Steinkamp's method, mithramycin fluorescence intensity indicates DNA content, while the **difference signal**, i.e., mithramycin fluorescence minus Hoechst fluorescence, provides a measure of the amount of BrUdR incorporated. The electronic subtraction magnifies the differences between fluorescence from the quenched and unquenched DNA fluorochromes; however, the results are probably cleaner than might be obtained by using a difference signal between Hoechst dye and propidium and ethidium fluorescence. This is so because ethidium and propidium themselves substantially quench Hoechst dye fluorescence, decreasing its intensity considerably and generally leading to lower measurement precision; mithramycin does not quench Hoechst dye fluorescence to nearly the same extent. The **ratio** of mithramycin fluorescence to Hoechst dye fluorescence may also be used to provide the measure of BrUdR incorporation. While Crissman and Steinkamp developed this technique with Los Alamos' multibeam flow cytometer, using very large argon and krypton ion lasers for excitation, it is perfectly feasible to measure the relatively bright fluorescence from Hoechst 33342 and mithramycin-stained cells in instruments using more modest light sources, e.g., a Cytomutt equipped with an air-cooled He-Cd laser emitting 325 nm and 441 nm simultaneously (I've tried this dye combination and light source with excellent results) or a multibeam (365 and 436 nm) Hg arc lamp system<sup>88,844</sup>.

### Breaking Up Is Easy To Do: SBIP, a Simpler Way to Detect BrUdR Incorporation into DNA

A 1994 publication by Li et al<sup>1666</sup> from Darzynkiewicz's lab described a greatly simplified method for detection of BrUdR incorporation. BrUdR acts as a photosensitizer for DNA; UV illumination of DNA containing the label leads to strand breaks at the sites of incorporation. After exposure to BrUdR, cell suspensions in Petri dishes are illuminated for 5 min with 300 nm light by placing them atop an analytical DNA transilluminator. The DNA strand breaks induced by illumination are then labeled by incorporation of digoxigenin- or biotin-labeled dUTP, with terminal deoxynucleotidyl transferase (TdT) added to catalyze the reaction. The labeled dUTP can then be detected using fluoresceinated anti-digoxigenin antibodies or fluorescein-*streptavidin*. Results obtained using the newer **SBIP (Strand Breaks Induced by Photolysis)** method and the standard technique employing anti-BrUdR antibodies are compared in Figure 10-4, on the next page.

The major advantage of the SBIP method is that it does not require DNA denaturation; this allows phycoerythrin antibodies to be used to detect cell surface or intracellular antigens, which might be destroyed during denaturation.

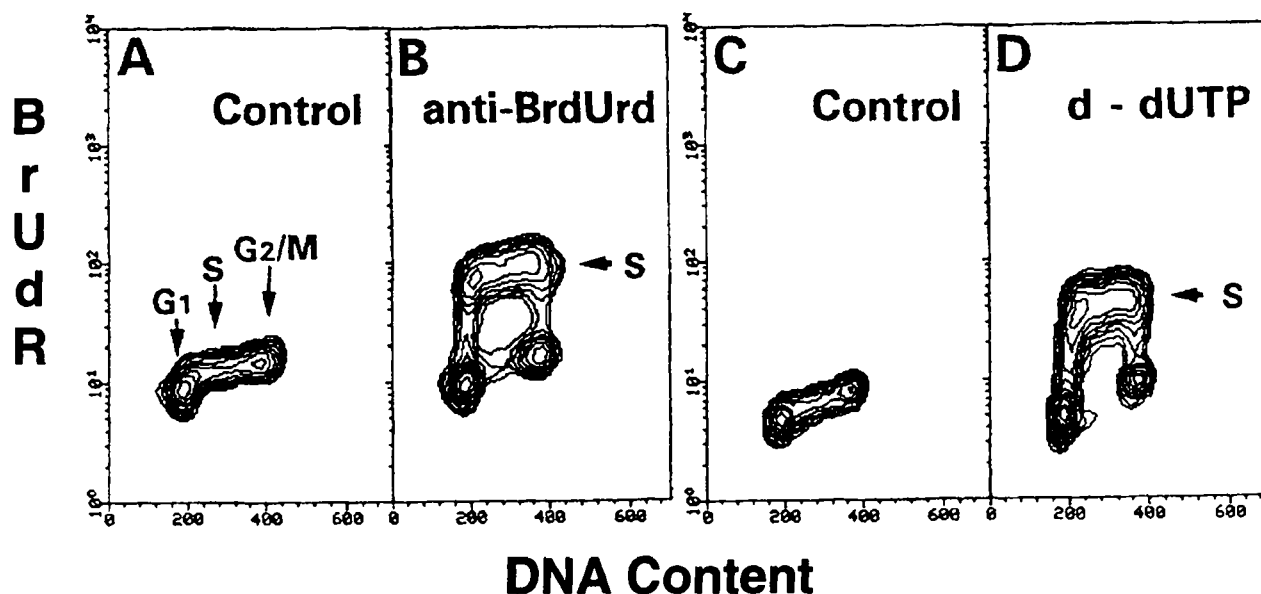

Figure 10-4. Detection of BrUdR incorporation using anti-BrUdR antibody (A and B) and the SBIP method (dUTP labeling of strand breaks induced by photolysis) (C and D) in HL-60 cells grown in the presence (B and D) and absence (A and C) of 50  $\mu$ M BrUdR for 1 h. The x-axis shows DNA content, indicated by propidium fluorescence, on a linear scale; the y-axis shows BrUdR content, indicated by fluorescein fluorescence, on a logarithmic scale. The figure, reproduced with permission, is from X Li et al, *Intl J Oncology* 4:1157-61, 1994<sup>666</sup>, and was provided by Zbigniew Darzynkiewicz (New York Medical College).

Unlike the Hoechst/PI and Hoechst/mithramycin techniques, the SBIP method requires only 488 nm illumination. The method can also be adapted to distinguish between strand breaks due to apoptosis and to BrUdR, permitting simultaneous analysis of apoptosis and DNA synthesis<sup>2074</sup>. Further refinements of the SBIP technique were introduced in 1995. It was noted<sup>2946</sup> that prior incubation with Hoechst 33258 increased the number of strand breaks produced during a given period of UV illumination; it was also possible to incorporate BODIPY- or fluorescein-labeled dUTP rather than digoxigenin- or biotin-labeled dUTP at strand breaks, eliminating the need for the addition of fluorescently tagged anti-digoxigenin antibody or streptavidin to produce detectable labeling. However, in another paper published the same year<sup>2947</sup>, the authors reported that BrdUTP, which is much less expensive than dUTP labeled with biotin, digoxigenin, BODIPY, or fluorescein, was efficiently incorporated at strand break sites and was readily detected by fluoresceinated anti-BrUdR antibodies, producing signals severalfold brighter than those obtained using directly or indirectly tagged nucleotides.

The application of the SBIP method to cells labeled with a tracking dye such as CFSE (see pp. 372-4) should allow derivation of cell cycle phase information in five or more successive generations of cells, surpassing the capacities of the Hoechst/PI method in this regard.

When I wrote the previous edition of this book, I was sure that the SBIP technique would replace methods that used anti-BrUdR antibody to detect BrUdR incorporation.

However, within a year or two, the SBIP method was modified to use anti-BrUdR antibody, and the story doesn't end there.

#### Anti-BrUdR Antibody: Seeing the Light

The major objection to the original anti-BrUdR antibody methods arose because it was necessary to denature the DNA in order to get the antibody to react with incorporated BrUdR. A few years after the SBIP method was published, light bulbs lit up in the heads of Hammers, Kirchner, and Schlenke<sup>2948</sup>, who reported in 2000 that the DNA denaturation step could be eliminated by incubating the cells with Hoechst 33258 and irradiating them with UV light, as was done in the SBIP method. They found that if the cells were then transferred to a hypotonic (68 mOsm) buffer, anti-BrUdR antibodies would bind to the incorporated BrUdR. UV-A, UV-B, and UV-C sources were tested; light at 280-320 nm from an 8 W UV-B bulb yielded the best results.

#### Cytochemical Detection of BrUdR: Still Around

The anti-antibody folks haven't been resting on their laurels since the previous edition appeared, either. Frey<sup>2620</sup> noted in 1994 that the fluorescence of both LDS-751 and TO-PRO-3 was enhanced in the presence of DNA into which BrUdR had been incorporated. LDS-751 can be excited at 488 nm and emits at 670 nm; staining cells with a combination of LDS-751 and propidium can therefore be used to detect BrUdR incorporation using only a 488 nm excitation beam. As it happens, it is also possible to use a

single 488 nm excitation beam for cells stained with a combination of propidium and TO-PRO-3, because there is enough energy transfer from propidium to TO-PRO-3 to produce a usable signal. Beisker et al<sup>2949</sup> used dual-laser instrument with a 488 nm beam exciting propidium fluorescence and red He-Ne or diode lasers exciting TO-PRO-3 fluorescence in isolated nuclei, and found that concentrations of 50  $\mu\text{M}$  propidium and 0.3  $\mu\text{M}$  TO-PRO-3 provided the best compromise between BrUdR detection sensitivity and DNA histogram resolution. Some of their results appear below in Figure 10-5.

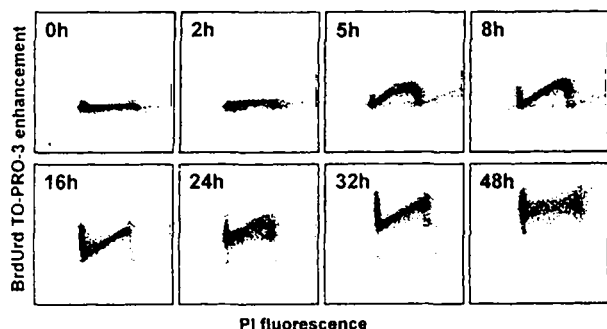

Figure 10-5. Use of a combination of propidium and TO-PRO-3 to detect bromodeoxyuridine incorporation. Propidium fluorescence (insensitive to BrUdR incorporation) is shown on the X-axis; the Y axis shows the quotient of TO-PRO-3 and propidium fluorescence. From W. Beisker et al, *Cytometry* 37:221-9, 1999 (Reference 2949), © John Wiley & Sons, Inc., used by permission.

Cytochemical detection of BrUdR incorporation is somewhat less sensitive than detection using antibody and/or strand break techniques; cells are typically incubated with concentrations of 20-60  $\mu\text{M}$  BrUdR, which may affect cell growth. However, cytochemical detection could, at least in principle, make it possible to assess BrUdR incorporation in viable cells, which is not possible when either antibody or strand break techniques are used.

Mozdziaik et al<sup>2950</sup> found it possible to enrich cells with and without BrUdR to a purity of over 90% when sorting from mixtures of cells stained with Hoechst 33342 alone, but it was difficult to assess fractions of cells in different phases of the cell cycle in the BrUdR-containing cell population because fluorescence intensity was low. I am not aware of any reports in the literature on the interaction of DRAQ5<sup>2338-9</sup> with DNA containing BrUdR. DRAQ5 is the only dye other than Hoechst 33342 and a few other Hoechst dyes that has been reported to stain DNA stoichiometrically in living cells. If DRAQ5 fluorescence is either unaffected by the presence of BrUdR in DNA or enhanced by it, it should be possible to use a combination of Hoechst 33342 and DRAQ5 with UV and 488 nm or red excitation to measure BrUdR incorporation and cell cycle position simultaneously in viable cells.

If you have any experience with nucleic acid sequencers, you are likely to be aware that at least some of them work by incorporating fluorescently labeled nucleotides into oligonucleotides. Wouldn't it be nice if we could put those fluorescently labeled nucleotides into DNA *in vivo*? Yup. But we can't, at least not yet.

### Label or Slander?

While we tend to regard established methods as having more of a ring of truth about them than newer ones, it is apparent that techniques based on incorporation of tritiated thymidine or other radioisotopes are not themselves without warts. High specific activity thymidine may administer enough radiation therapy to cells exposed to it to affect their rate of progress through the cell cycle. Also, the validity of many studies involving measurements of isotope uptake rests on assumptions that pool sizes remain constant and that the isotope used is not reutilized or metabolized. This has certainly not been established for every cell system studied with radioisotopes. One of the few published papers that compared the two kinetic methods found marked discrepancies between the fraction of stimulated thymocytes, as assessed by flow cytometry, in con A-treated and control cultures and the amounts of radiolabeled thymidine taken up<sup>396</sup>. Labeling experiments with BrUdR may be helpful in explaining results such as this. On the other hand, BrUdR can induce apoptosis in cells<sup>1666</sup>, and, as noted above, it can inhibit growth at high concentrations, so it's not completely above suspicion, either.

### Detecting RNA Synthesis Using Bromouridine

While I am still close to the subject of anti-BrUdR antibodies, I should point out that, according to Jensen, Larsen, and Larsen<sup>1667</sup>, RNA synthesis can be detected relatively readily using these antibodies, which cross-react with bromouridine incorporated into RNA.

### Generation Gaps: Tracking Dyes and Cell Kinetics

Tracking dyes have been introduced on pp. 45-6 and 371-4, and will be discussed further in the section on immunology later in this Chapter (p. 501). CFSE, in particular, allows viable cells in different generations to be identified and sorted, at least when used at relatively low concentrations. Tracking dyes offer an attractive alternative to BrUdR for labeling and following cells through generations, because, to date, getting the answers from BrUdR requires killing the cells. On the other hand, tracking dyes can't answer the question of whether or not a cell is synthesizing DNA over a short time period; we'll still need BrUdR or something like it to do that job, and, if we're working with pulse-labeled cells, we're likely to have to sacrifice the cells to get the answers.

### Cell Cycle-Related Proteins: Cyclins, Etc.

Variations in many cellular characteristics during the cell cycle can be analyzed simply and directly by two-

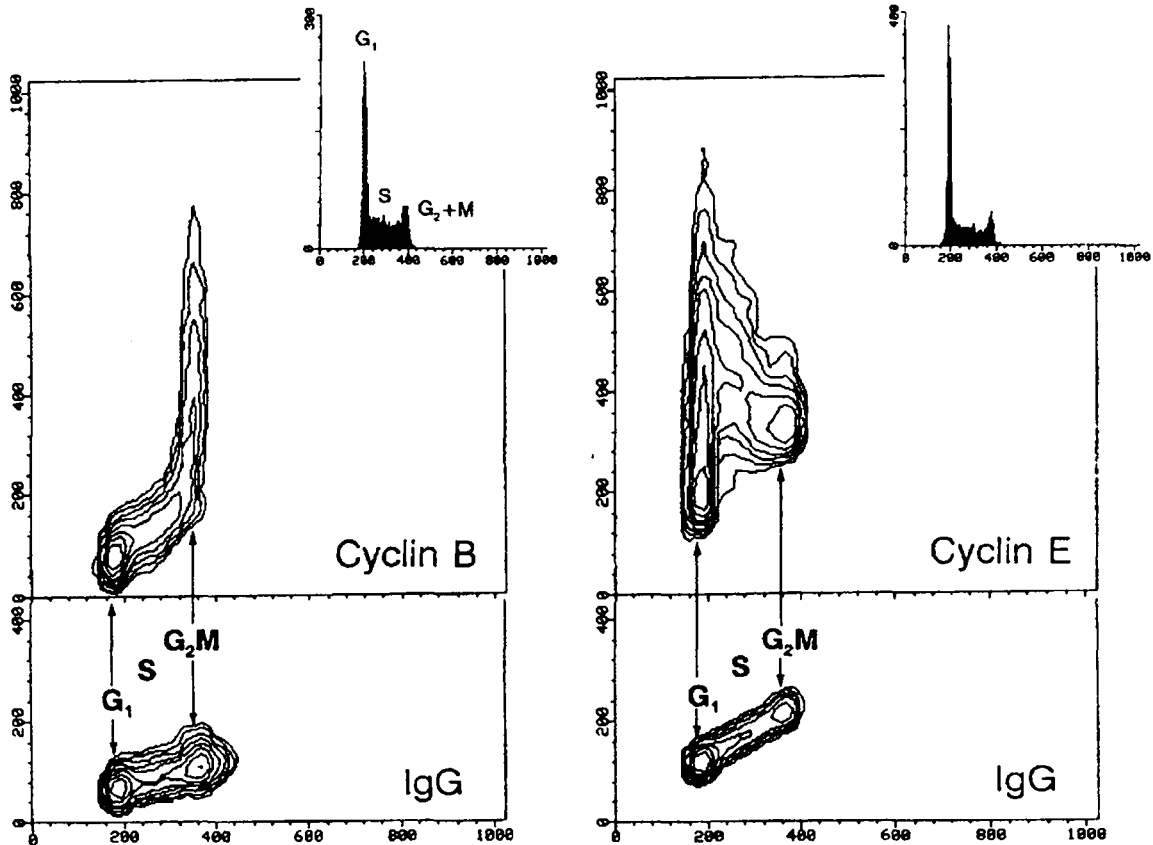

Figure 10-6. DNA content vs. expression of cyclins B and E in exponentially growing MOLT-4 cells; cells stained with nonspecific IgG instead of anticyclin antibodies are shown as controls. Cyclin B is expressed predominantly in late S, G<sub>2</sub>, and M phases; cyclin E expression, while more heterogeneous, is predominantly in G<sub>1</sub> and early S. The figure, provided by Zbigniew Darzynkiewicz and used by permission, is from a paper by Gong, Traganos, and Darzynkiewicz<sup>1850</sup> (Int'l J Oncology 3:1037-42, 1993).

parameter flow cytometry of cells or nuclei stained simultaneously with a DNA fluorochrome and with a fluorescent probe that allows quantification of the other parameter being investigated.

In cells growing actively and continuously without maturation, the mass and volume of all cellular constituents must double over one cycle of growth. With the aid of DNA fluorochromes, we can observe the doubling of DNA content during the cell cycle. When we look at the joint distribution of any other cellular constituent and of DNA content in growing cells, we thus have to expect that, whatever the other constituent may be, there should be twice as much of it in M phase cells as there is in G<sub>1</sub> phase cells. This does not, however, always mean that the data points in the bivariate distribution lie along or about a straight line.

A strict linear relationship between cells' content of DNA and of another constituent can exist only if the constituent is synthesized at the same rate as is DNA. Deviations from such a relationship, such as are shown in Figure 10-6, indicate that a constituent is synthesized or expressed preferentially in one or more phases of the cell cycle, as is the

case for **cyclin B** (predominantly expressed in late S, G<sub>2</sub>, and M) and **cyclin E** (predominantly expressed in G<sub>1</sub> and early S, although the pattern of expression is more heterogeneous than that seen for cyclin B)<sup>1850,1</sup>. Note that the IgG controls in Figure 10-6, in which staining by antibody is nonspecific and should therefore be predominantly size-dependent, do show a linear relationship between antibody fluorescence and DNA content.

Darzynkiewicz et al<sup>2951</sup> reviewed the cytometry of cyclins in 1996. Cyclins B and E have been mentioned above; **Cyclin A** is expressed in S and G<sub>2</sub>, but is lost in mitosis just prior to metaphase, while **cyclin B<sub>1</sub>** is lost between metaphase and anaphase<sup>2952</sup>. **D-type** cyclins are expressed early in G<sub>1</sub>. It is inadvisable to use the presence or absence of various cyclins as an indicator of precise position in the cell cycle<sup>2953</sup>. This caution applies especially when working with tumor cells or with cells subjected to the influence of various agents that perturb the cycle; deviations from the "schedule" may occur in either case.

The distribution shown in Figure 3-10 (p. 97) and in Figure 7-16 (p. 321), to which I usually refer as the

“Darzynkiewicz Flag,” is one that is commonly encountered in analyses of RNA<sup>213,262-3,753-6</sup>, total protein<sup>297,522,753-6</sup>, and nuclear protein<sup>523,750-2</sup> content during the cell cycle. Zbigniew Darzynkiewicz has, over the years, consistently been among the first to develop new methods for studying the birth and death of cells and to apply those methods to the study of cancer and other diseases, as should be obvious from the frequency with which his work is cited in this and previous editions of this book.

While RNA and protein are not synthesized continuously during the cell cycle, the rates of synthesis of these two constituents do track one another<sup>899</sup>. Roti Roti et al<sup>523</sup> have used the distribution of nuclear protein vs. DNA content to divide the cell cycle into early and late G<sub>1</sub>, early and late S, and early and late G<sub>2</sub> compartments; they were able to detect cell cycle-specific synthesis of nuclear proteins by measuring incorporation of radiolabeled precursors into sorted nuclei *in vitro*<sup>1852</sup>.

Distributions obtained from simultaneous analysis of DNA content and of antigens that are expressed primarily during S phase<sup>524,960</sup> exhibit the pattern of panels B and D in Figure 10-5 (p. 457); these were actually obtained when anti-BrUdR antibody and dUTP, respectively, were used to detect cells in S phase<sup>491-4,834-6,1066</sup>.

Since the previous edition of this book was written, our understanding of molecular mechanisms involved in progression through the cell cycle has continued to increase, with the 2001 Nobel Prize in Medicine being awarded to Leland Hartwell, Tim Hunt, and Sir Paul Nurse “for their discoveries of key regulators of the cell cycle.” Analyses of DNA content and of antigens that are differentially expressed during different phases of the cell cycle remain of great interest to clinicians as well as to basic researchers.

An intracellular antigen defined by the Ki-67 monoclonal antibody<sup>1792,1661,1853-4</sup> is preferentially expressed in proliferating cells (G<sub>1</sub>, S, G<sub>2</sub>, and M phases, but not G<sub>0</sub>). The Ki-67 antibody came from the clone in the 67th well of a 96-well plate at the University of Kiel, which contained hybridomas resulting from immunization of mice with cells from Hodgkin’s lymphomas. The Ki-67 antigen is not found in cells undergoing DNA repair or in tumors with unscheduled cyclin expression, and is considered a robust marker of cell proliferation; levels of Ki-67 expression are of prognostic value in at least some tumor types<sup>2954</sup>.

The presence of proliferating cell nuclear antigen (PCNA)<sup>1855-9</sup> is also used to identify proliferating cells; this antigen is most prominently expressed during S phase. Landberg and Roos<sup>1858</sup> have developed no-wash staining techniques for unfixed cells facilitating demonstration of nuclear antigens; they have also shown that dual staining with Ki-67 and anti-PCNA antibodies identifies discrete G<sub>0</sub>, G<sub>1</sub>, S, G<sub>2</sub>, and M phase compartments of the cell cycle. Teague and El-Naggar<sup>1859</sup> compared three monoclonal antibodies and two fixation protocols for analysis of PCNA, and found the most reliable determinations were obtained using methanol fixation and the PC10 antibody (DakoCytoma-

tion), which reacts with PCNA even in paraffin-fixed material. Larsen et al have recently reviewed the subject of PCNA detection<sup>2955</sup>.

Transferrin is required for cell growth<sup>2956</sup>, and proliferating cells express the transferrin receptor (CD71) on their cell surfaces. In well-defined experimental systems, e.g., mitogen- or antigen-stimulated lymphocytes, substantial CD71 expression is detectable on cells in the G<sub>1</sub>, S, G<sub>2</sub>, and M phases of the cell cycle, but not on G<sub>0</sub> cells (Figure 10-7).

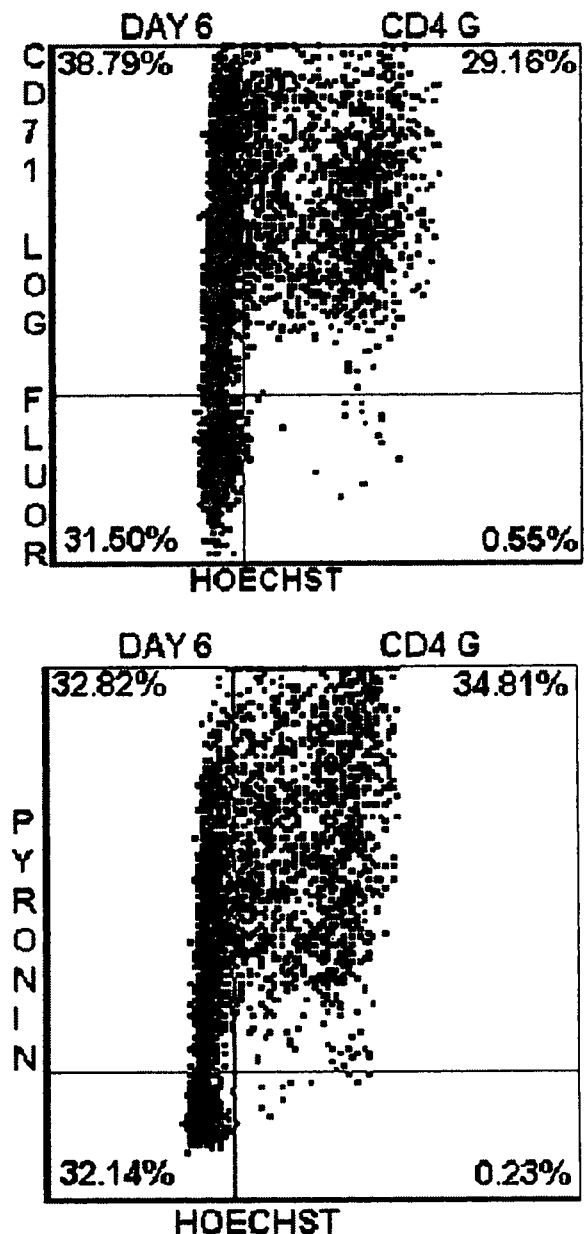

Figure 10-7. CD4 Cells from a 6-day-old mixed lymphocyte reaction (MLR), showing DNA content (Hoechst 33342) vs. transferrin receptor (top panel; CD71 fluorescence, log scale) and RNA content (bottom panel; pyronin Y fluorescence, linear scale). Data are from Lucia Vasconcellos and Edgar Milford (Brigham and Women’s Hospital, Harvard Medical School).

Since it is, as a rule, easier to detect cell surface antigens than intracellular antigens, and since it is generally possible to preserve cell viability after detecting cell surface antigens, but not possible to do so after detecting intracellular antigens, it would seem to me that, if one wanted to demonstrate a proliferation-related antigen, CD71 would be a better choice than, say, Ki-67. However, while there seem to be numerous studies of Ki-67 expression on tumors<sup>2954</sup> and its relation to malignant potential, there are relatively few papers (reference 2957 is an example) that examine CD71 expression in this regard. There are also studies of Ki-67 in stimulated lymphocytes<sup>2954</sup>, and, when I hear people who have elected to use Ki-67 as an indicator of lymphocyte proliferation complaining about the difficulty of doing the measurements, I always ask why they didn't try CD71 instead. However, there does not seem to be a published study of lymphocytes or any other cell type in which flow cytometry was used to look at Ki-67 and CD71 in and on the same cells at the same time. I'll do one if I can get around to it, but it would be nice if somebody else got me off the hook.

Flow cytometry has also been applied to studies of **oncogene expression** and its effects on the cell cycle. Some of the earliest work was done by Jacobberger, Fogleman, and Lehman<sup>727</sup>, who had to develop and refine methods for demonstration of intracellular antigens as a first order of business. Lehman et al<sup>1860</sup> studied expression of the early tumor (T) and late viral (V) antigens in cells infected with simian virus 40 (SV40); the amount of T antigen per cell increased as cells entered successive stages of the cell cycle, while synthesis of V antigen began in late S and G<sub>2</sub> + M phases. Sladek and Jacobberger<sup>1861</sup> examined mouse fibroblasts after infection with a recombinant retrovirus encoding T antigen. As a result of T antigen expression, the duration of the G<sub>1</sub> phase was decreased and the duration of the G<sub>2</sub> + M phase was increased; the duration of S phase was unaffected by antigen expression. They subsequently established<sup>1862</sup> that T antigen is a concentration-dependent, positive cell cycle regulator in exponentially growing cells, and that endogenous negative control mechanisms responding to cell density override its effect. "Jake" Jacobberger and his colleagues continue to make significant contributions in this field<sup>2701-2,2958-61</sup>.

Darzynkiewicz et al<sup>262,525</sup> defined cell cycle compartments as G<sub>1a</sub> and G<sub>1b</sub>, according to whether RNA content has not or has reached the level associated with the earliest visible S phase cells. It was observed by Darzynkiewicz et al<sup>526</sup> that cell size (as estimated from light scatter measurements), RNA and protein content are all more heterogeneous (i.e., distributions of these parameters have higher CV's) in G<sub>1a</sub> than in G<sub>1b</sub> + M cell populations; this indicates an **unequal apportionment of cytoplasmic contents into daughter cells at cell division**. Most of the variance of the distributions of these parameters in cells in G<sub>1</sub> is contributed by cells in the G<sub>1a</sub> compartment. This was taken to indicate that the RNA and protein content of cells equalizes prior to the transition to G<sub>1b</sub>, in which compartment heterogeneity is minimal. The variance of distributions of fluorescence of a tracking dye

such as PKH26 in cells (Figure 7-23, p. 372) can serve as an indicator of unequal distribution of membrane lipid between daughter cells.

Kimmel, Traganos, and Darzynkiewicz<sup>527</sup> established that the duration of G<sub>1a</sub> is exponentially distributed and has a greater variance than the duration of G<sub>1b</sub>, and that all or nearly all daughter cells enter G<sub>1a</sub> following cell division. These findings support the transition probability model of cell kinetics proposed by Smith and Martin<sup>528</sup>.

**Relationships between cell size, DNA replication, and cell division** have been the subject of speculation over many years; a brief review<sup>529</sup> by Baserga and a report by Zetterberg, Engstrom, and Dafgård<sup>530</sup> raised interesting questions best answered by cytometry. Zetterberg's group examined the effects of different types of **growth factors** on 3T3 cells starved to quiescence in low-serum media. Epidermal (EGF) and platelet-derived (PDGF) growth factors stimulated quiescent cells to undergo DNA synthesis and mitosis, but there was no growth (with EGF) or little growth (with PDGF) in cell size during the replication period, and the daughter cells would not undergo further division. When insulin was added, both growth in size and DNA synthesis occurred, although addition of insulin alone did not stimulate cells to enter mitosis. Thus, there may be separate control mechanisms associated with cytoplasmic growth and DNA replication.

When the previous edition of this book appeared, the determination of **relationships between surface antigen expression and cell cycle compartments defined by both DNA and RNA content**, while of interest to many investigators, was readily possible only for those who had the dual beam UV/488 nm excitation capability needed for Hoechst/pyronin/fluorescein staining, although similar studies could be accomplished, with more preparative effort, with single-beam instruments, using a technique described by Bauer et al<sup>701</sup>, in which cells sorted on the basis of immunofluorescence are restained with acridine orange. It is now possible (pp. 324-5) to use the combination of 7-AAD and pyronin Y to determine DNA and RNA content in instruments with only a 488 nm illuminating beam, with fluorescein isothiocyanate or a fluoresceinated antibody, respectively, applicable to determination of total protein content or the content of a surface or intracellular antigen<sup>734,6</sup>. If you have a 3-beam instrument with 6-color capability, and you want to study the relationship of two or three antigens to one another and to the cell cycle, you don't have much excuse not to use Hoechst 33342 and pyronin Y (and/or CD71) to define cell cycle phases and discriminate G<sub>0</sub> cells from G<sub>1</sub> cells. That's what the instrument is built for, and you might as well get your money's worth.

Sinnott, Flint, and Lalande<sup>1863</sup> described a procedure for **determining the point during S phase at which any single-copy DNA sequence is replicated**. Cells are synchronized at the G<sub>1</sub>/S phase boundary, released and labeled with BrUdR, and sorted on the basis of DNA content at different times after release. Newly replicated BrUdR-substituted

DNA is then removed by UV irradiation and S1 nuclease treatment. PCR will thus not be able to amplify the target sequence in cells in which it has been replicated, while amplification, with production of detectable DNA, will occur in cells in which replication has not yet occurred.

### Detecting Mitotic Cells

On p. 454, I promised you a follow-up on detecting mitotic cells; it was mentioned on p. 277 that a combination of side scatter and propidium fluorescence might be usable for the purpose, and the use of acridine orange staining to define differences in chromatin structure between interphase and mitotic cells was described and illustrated (Figure 7-15) on p. 320. While it looked for a while as if cyclins A and B1 might be helpful, a 1998 study by Juan et al<sup>2962</sup>, from Darzynkiewicz's lab, established that an **antibody to phosphorylated histone H3 (anti-H3P)** reacted with mitotic cells, providing better discrimination than any of the anticyclin antibodies. In a 2001 review, Juan et al<sup>2963</sup> concluded that "the use of the H3-P antibody appears to provide the most advantages compared with the alternative methods of detection of mitotic cells"; this article provides protocols and caveats. By using antibodies to cyclins A and B1, in combination with anti-H3-P, it is possible, at least to some extent, to differentiate between early and late mitotic cells.

Figure 10-8, below, demonstrates identification of a mitotic population in cells stained with propidium iodide and anti-H3-P; the cells shown in the figure are those remaining after doublets were excluded by gating on a plot of peak vs. integral propidium fluorescence.

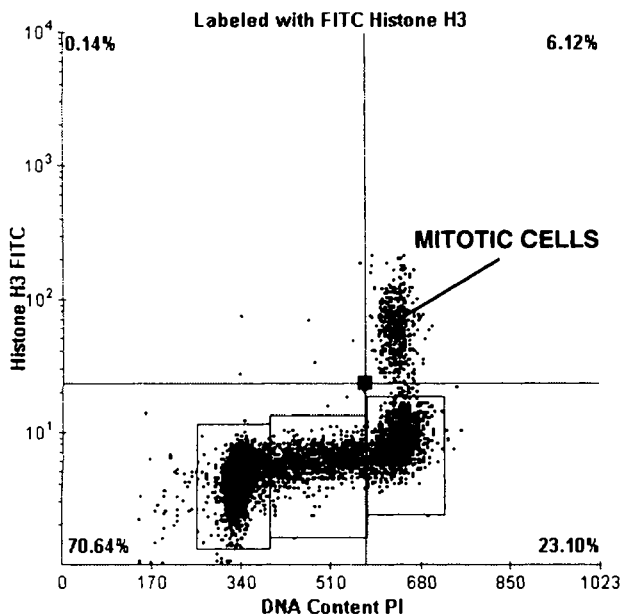

Figure 10-8. Identification of mitotic cells by staining with propidium iodide and antibody to phosphorylated histone H3. Courtesy of Jeffrey Scott and Dorothy Lewis (Baylor College of Medicine).

## Memento Mori: Detecting Cell Death

### Necrosis versus Apoptosis

There are two different mechanisms of cell death, **programmed cell death**, or **apoptosis**, and **accidental cell death**, or **necrosis**<sup>2352</sup>. **Necrosis** is identified primarily by **loss of membrane integrity**, as indicated by **dye exclusion tests**, which have been discussed in detail on pp. 46, 300-2, and 369-71.

**Apoptosis** seems to have aroused almost as much interest as sex, which is curious when you consider that, thanks to apoptosis, tadpoles lose a little tail. Apart from its role in embryonic development, apoptosis has been implicated in AIDS and cancer, and techniques for detecting apoptotic cells by cytometry, flow and otherwise, continue to be proposed by numerous investigators.

Comprehensive reviews of the subject by Darzynkiewicz et al appeared in 1992<sup>1517</sup> and 1997<sup>2352</sup>; in the latter, the term **cell necrobiology** was introduced "to comprise various modes of cell death; the biological changes which predispose, precede, and accompany cell death; as well as the consequences and tissue response to cell death. The term combines [the Greek] *necros* ("death") with *bios* ("life")."

### Identifying Apoptotic Cells

The term "apoptosis" itself derives from a Greek word that describes phenomena such as the falling of leaves from trees. When, in 1997, I was inspired to wax lyrical about apoptosis, there was only one melody to use:

#### Les Feuilles Mortes (Autumn Leaves)

When outer leaflets of cell membranes  
Let phosphatidylserine show,  
Labeled annexin V will bind there,  
And you can measure it in flow<sup>2353-4,2963-4</sup>.

Mitochondria deenergize<sup>2811-6,2965</sup>,  
And superoxide levels rise<sup>2966-8</sup>,  
But the nuclear signs of apoptosis<sup>1517,1521-4,1526</sup>  
Come later<sup>2352</sup>; then, the cell dies.

Did thymocytes get radiation?  
Was dexamethasone to blame?  
Or was it simply Fas ligation?  
The end results are all the same.

Lytic enzymes in the cell are loosed<sup>2557,2769-72</sup>;  
Less glutathione stays reduced<sup>2815,2967</sup>,  
And, around the time the membrane's leaky<sup>1520,1525,1527-31</sup>,  
The vultures all leave their roost.

The journals publish three new assays  
For apoptosis every week<sup>2971-83</sup>;  
Is it biology that varies  
From cell to cell<sup>2984-5</sup>, or just technique<sup>2986</sup>?

Cells can stay alive, as good as new,  
 If they can make bcl-2<sup>2969</sup>,  
 But, if not, their DNA's in fragments<sup>1517-9,2971,2982-3,2985</sup>  
 When apoptosis is through.

(©Howard Shapiro; used by permission)

### Apoptosis: Getting With the Program

In their 1992 review, Darzynkiewicz et al<sup>1517</sup> reported that the ATP-dependent lysosomal proton pump, demonstrated by supravital uptake of acridine orange, was preserved in apoptotic but not necrotic cells, and that bivariate analysis of cells for DNA and protein showed markedly diminished protein content in apoptotic cells, probably due to endogenous protease (what we now know to be caspase) activation. The sensitivity of DNA *in situ* to acid denaturation, probed by staining with acridine orange at low pH (see p. 320), was increased in both apoptotic and necrotic cells. They also reported that **mitochondrial membrane potential ( $\Delta\Psi_m$ )**, which they assayed by retention of rhodamine 123, was preserved in apoptotic, but not in necrotic cells; this is at variance with later findings by numerous other groups<sup>281-6,2963,2969</sup>. The anti- and proapoptotic proteins in the bcl-2 family are associated with mitochondria, and it is now generally appreciated that **induction of mitochondrial permeability is one of the earliest events in apoptosis**. While there are disputes about which technique(s) is/are best to demonstrate loss of  $\Delta\Psi_m$  (see pp. 394-400), this parameter is now widely used to detect apoptosis. Changes in **reactive oxygen species** occur<sup>2966-8</sup>, but are not as widely used as indicators.

As was noted on p. 380, both fluorogenic substrates and inhibitors can be used to detect the activity of **caspases**, which are the prime enzymatic movers of events in apoptosis<sup>2332,2556-7,2769-72</sup>.

### ISNT there Light at the End of the TUNEL?

In apoptosis, but not necrosis, activation of an endonuclease results in fragmentation of DNA, which produces a characteristic "ladder" on gel electrophoresis. DNA fragmentation can be detected directly in cells using **in situ nick translation (ISNT)**<sup>1518-9,2982</sup> or **TdT(terminal deoxynucleotidyl transferase)-mediated biotin-dUTP nick-end labeling (TUNEL)**<sup>1519,2971</sup> assays. In both types of assay, cells are permeabilized, and dUTP labeled with fluorescein, digoxigenin, or biotin or, alternatively, BrdUTP is incorporated at the site of strand breaks. DNA polymerase I is used to catalyze incorporation in nick translation assays; however, incorporation is said to proceed more rapidly in TUNEL assays, in which TdT is used as catalyst<sup>1519</sup>. Fluoresceinated dUTP is detected directly; biotin- and digoxigenin-dUTP are, respectively, detected using labeled streptavidin and labeled anti-digoxigenin antibodies, and BrdU is detected with anti-BrdU antibodies. As was noted in the discussion of BrdUR labeling of DNA on p. 457, BrdUTP is a lot cheaper than other labeled nucleotides; it now seems to be very popular for TUNEL assays for the same reason.

Plasma membrane integrity is lost early in necrotic but not apoptotic cells; the former take up propidium iodide (PI) after a brief exposure, while the latter do not. However, apparent membrane permeability is slightly increased in apoptotic cells, resulting in different patterns of uptake of several dyes as compared to intact cells. Apoptotic cells stain faintly with ethidium<sup>1527</sup> and 7-AAD<sup>1517</sup>, and take up propidium after a moderate incubation period<sup>1528</sup>. Hoechst dye uptake is increased, as is efflux of fluorescein produced by FDA hydrolysis<sup>1529</sup>. Changes in scatter signals occur in association with membrane permeability changes; apoptotic cells have lower forward and higher side scatter signals than do intact cells<sup>1520-1,1523,1525,1530</sup>.

If you happen to have a flow cytometer with dual-beam UV and 488 nm excitation, the combination of PI and Hoechst 33342 provides good discrimination of live, necrotic, and apoptotic cells<sup>1530</sup>; live cells show low Hoechst dye fluorescence and high forward scatter, apoptotic cells show higher Hoechst dye fluorescence and lower forward scatter, and necrotic cells exhibit high PI fluorescence and low forward scatter. The use of a PI/7-AAD combination facilitates analysis of apoptosis in populations defined by fluorescein and phycoerythrin immunofluorescence<sup>1531</sup>. If you only have one beam, all is not lost; Schmid et al<sup>1517</sup> report that 7-AAD and scatter can distinguish apoptotic cells, and this technique can also be used with two-color immunofluorescence. Necrotic (or late apoptotic) cells take up a substantial amount of 7-AAD, intact cells take up little or none, and apoptotic cells take up a small amount.

Low molecular weight DNA is lost after cell permeability increases, resulting in decreased staining of apoptotic cells by DNA-specific fluorochromes, producing a **hypodiploid (sub G<sub>0</sub>/G<sub>1</sub>) peak**<sup>1520-6</sup>. This staining pattern is observed using a wide variety of DNA fluorochromes<sup>1527</sup>. However, in a flow cytometric analysis, one can never be sure that the sub G<sub>0</sub>/G<sub>1</sub> events observed in a DNA histogram represent cells rather than apoptotic bodies (nuclear fragments); this makes it difficult to arrive at a reliable measure of the fraction of apoptotic cells by DNA analysis.

It should be appreciated that the features of apoptosis differ in at least some particulars from cell type to cell type (for example, see references 2984-6); this helps explain why assays developed using one or two cell types and one or two inducers of apoptosis may fail ingloriously when attempts are made to apply them to different model systems.

### Apoptosis: The Case Against Flow Cytometry

Darzynkiewicz et al<sup>2983,2986</sup> point out that apoptosis is a dynamic process, sometimes resulting in the complete dissolution of cells within a few hours, and that many of the criteria required to precisely define the occurrence and extent of apoptosis in cell populations are morphological. For this reason, they now favor **laser scanning cytometry**<sup>2382,2983,2986</sup> over flow cytometry for studies of apoptosis, pointing out that this allows you to "have your cake and eat it too"<sup>2986</sup>. They do, however, have a favorite flow cytometric method,

the **stathmo-apoptosis** method<sup>2770,2987</sup>, in which a fluorescent irreversible caspase inhibitor, FAM-VAD-FMK, is added to cultures to arrest apoptosis, preventing cell disintegration. A **cumulative apoptotic index (CAI)** can be measured over periods as long as several days; cells are not prevented from undergoing the earliest stages of apoptosis, but, once they reach the stage of caspase activation, they bind the inhibitor, becoming fluorescent, and remain detectable.

### Die Another Day: Cytometry of Telomeres

The maintenance of telomere length appears to be required for immortalization of tumors and cell lines<sup>2988</sup>. Methodology has been developed for measurement of telomere length by both flow cytometry<sup>2715-6,222991-4</sup> and image analysis<sup>2989-90</sup>. PNA probes (p. 362) are used. It is important to know the DNA index or chromosomal ploidy of the cells being studied in order to correct flow cytometric measurements of total telomere probe fluorescence for the number of chromosomes present in cells.

## 10.3 IDENTIFICATION OF CELLS IN MIXED POPULATIONS

**Cell identification**, in one form or another, is involved in almost all flow cytometry; indeed, it was the prospect of developing automated cell identification methods for **hematology** and **cancer cytology** that provided the impetus and the funding for the development of the first flow cytometers.

Automating a cell identification procedure, whether or not flow cytometry is the method used, requires, first, that there be a reasonably well-accepted **taxonomy** or **classification scheme** in place for the cells of interest, which allows cells to be classified on the basis of **cellular characteristics** or **parameters** which can be measured by the apparatus to be employed. In addition to being able to discriminate one type of cell from another, this apparatus must, of course, also be able to discriminate cells from other, irrelevant objects in samples.

### Mixed Genotypes versus Mixed Phenotypes

The mixed cell populations encountered in cytometry are of two basic types. Marine biologists are likely to be working with samples containing **different genera and species** much of the time, and, not surprisingly, often rely on detection of differences in gene sequence to discriminate among cell types. Hematologists, on the other hand, are looking primarily at **phenotypic variation**. The fertilized ovum is the ultimate stem cell; while gametes, lymphocytes, and neoplastic cells may deviate significantly from the stem cell genotype, cytometric identification of different cell types in samples taken from blood, bone marrow, and the organs of the immune system is almost always based on differences in the amounts of gene products expressed.

### No Parameter Identifies Cancer Cells

In the area of **cancer cytology**, we did not know when cytometry started, nor do we know now, **what distinguishes**

**a malignant cell from a normal one**. After more than thirty years of intensive work in flow and image cytometry, cytochemistry, immunology, and molecular biology, we haven't found one constant difference, although we have described many characteristics in which some cancer cells differ from their normal counterparts. Where the difference has been defined, flow cytometry may help define whether it exists or not. As to the question, "What is a cancer cell?," it seems likely that the answer will be more in the form familiar to lawyers – "It is sometimes this, and sometimes that, and not this, and the other thing, or the third thing, in the presence of a fourth..." – than in the succinct form sought by physicians, medical scientists, the media and the public.

### Many Parameters Identify Blood Cells

When it came to **classifying blood cells**, we knew, or thought we knew, many of the answers. Even before we were able to identify hematopoietic stem cells, there was a taxonomy of blood cells in place; this classification was based primarily on the appearance under the transmitted light microscope of cells stained with various eosin-methylene blue-azure dye mixtures such as **Giemsa's** and **Wright's stains**, and supported by subsequent demonstrations of cytochemical differences between different cell types, for example, differences in the content or activity of various enzymes.

### Flow Cytometric Parameters Useful for Blood Cells

In order to develop automated instrumental methods of identifying blood cells, it was necessary to define **sets of cellular parameters** that could be measured by the apparatus and from which cells could be precisely identified using classification algorithms. Among the parameters found useful were **intrinsic parameters** such as **cell size**, **cytoplasmic granularity**, and **hemoglobin content**, and **extrinsic parameters**, including relatively nonspecific characteristics such as **affinities for various acidic and basic dyes** and more specific ones such as **glycosaminoglycan content** and **lipase and peroxidase activities**. By the early 1970's, when laser source flow cytometers were first used for cell surface immunofluorescence measurements, the other parameters just mentioned, singly or in combination, could be measured by image analysis or flow cytometry, and used to discriminate among **erythrocytes**, **lymphocytes**, **monocytes**, and **granulocytes**, and to distinguish **basophil**, **eosinophil**, and **neutrophil granulocytes**.

It was considerably more difficult to use any of the existing cell identification parameters to determine the **stage of maturity** of blood cells; it was similarly not possible to use these parameters to reliably distinguish any morphologic or biochemical differences between **lymphocyte subpopulations**, even when techniques such as rosetting were used to prepare samples enriched in one lymphocyte class or another. Within a few years of their introduction, **flow cytometric immunofluorescence measurements** were used to establish a taxonomy of lymphocytes; they have since been used to revise the genealogy of other blood cell types.

## Specific Gene Products Identify Cell Types

The success of immunologic methods should not lead any of us to the conclusion that fluorescent antibodies are the only specific reagents. The general strategy for defining and identifying different cell types, whether or not the different cell types are from the same organism, is to demonstrate the presence, and/or measure the amount(s), of one or more **specific gene products** in or on cells, ideally with minimal perturbation of the cells, or, more to the point, with a minimum of effort expended in sample preparation. If the specific gene product happens to be intracellular hemoglobin in red cells, it can be demonstrated with just about as much specificity by its absorption of violet light as it can be by immunofluorescence. If the gene product in question is an enzyme, a chromogenic or fluorogenic substrate may be used to demonstrate its activity. If one wants to identify blood basophils, the metachromatic staining of glycosaminoglycans in their cytoplasmic granules can be demonstrated at least as easily as can the presence of IgE receptors on their cell surfaces. When the going gets tougher, for example, if one wants to discriminate between different types of hemoglobin in red cells, then antibodies certainly offer us one way of doing the job, but the molecular biologists would probably just as soon go looking for specific messenger RNAs.

If one is looking at **mixed populations of cells of different species**, as in flow cytometric analysis of phytoplankton, it is reasonably likely that a suitable combination of parameters can be found which will unequivocally distinguish one cell type from another; the multidimensional distribution of the set of parameters will be **multimodal**, showing **discrete clusters** representing the individual cell types. Multimodal distributions may sometimes, but not always, also be obtained from **mixed populations of mature cells from a single organism**, as in differential leukocyte counting in normal peripheral blood. By definition, cells from a single organism have a common precursor in the fertilized ovum; what we term **differentiation** describes the process by which different genes are activated in different cells, with each cell type producing its own specific set of gene products which make it **biochemically and/or morphologically different** from other cell types.

### Maturation Processes and "Missing Links": The "Ginger Root" Model

**Discrimination among cell types with a common precursor** is particularly difficult when samples come from the anatomic compartment in which cell differentiation occurs. In peripheral blood, for example, it is trivial to distinguish red cells, which lack nuclei, from leukocytes, which have them, e.g., by measuring light scatter and the fluorescence of a DNA stain in nuclei. It is only slightly harder, using the right parameters, e.g., forward and side scatter, to separate monocytes and granulocytes, which have common precursors well beyond the primitive stem cell stage. In the marrow, enucleated red cells could clearly be told apart from

their late nucleated precursors by a combination of hemoglobin absorption and nuclear fluorescence measurements, but the earliest red cell precursors, containing little hemoglobin and not much more of other characteristic gene products, could not easily be distinguished from primitive cells of the leukocytic series. Similarly, given the presence in the marrow of their common precursors, we have no parameters that can define separate clusters of monocytes and granulocytes. Finally, in the peripheral blood, although we can tell erythrocytes and granulocytes from other cell types, the vagaries of measurement make us unable, **using any parameter**, to make unequivocal distinctions between reticulocytes, which contain detectable RNA, and mature erythrocytes, which don't, or between stab (band) and segmented polymorphonuclear cells, where an arbitrary nuclear morphologic criterion is normally used.

This problem arises whenever we observe **continuous processes of maturation or transformation**. We conceptualized mature leukocytes into discrete categories, with some justification; we also conceptualized the process of differentiation into discrete stages, which was much more of an idealization. There aren't transitional stages between eosinophil and basophil granulocytes; there have to be transitional cells between metamyelocytes and mature granulocytes because no cell division occurs past the metamyelocyte stage. No matter which parameters we examine, continuous processes give us continuous distributions. If we do multiparameter flow cytometry of leukocytes in normal peripheral blood, we see clusters; if we look at marrow, we get something which I once described as resembling a **ginger root**, incidentally prompting Mike Loken to find and demonstrate a ginger root of suitable morphology to illustrate the point. Another appropriate analogy might be to a hand and fingers; the peripheral blood shows us five disconnected fingerprints, while the marrow yields a handprint, in which the fingertips are seen to be connected to the palm.

A similar problem can exist in numerical taxonomy of species, which has also relied heavily on multivariate statistics. If one looks only at modern forms, one is likely to find distributions of measurement parameters containing discrete clusters representing individual species, even when those species have a common ancestor. If the analysis is extended to include older and extinct species, connections between clusters appear; the distribution takes on a "ginger root" character.

The nodular appearance of ginger roots is what makes them particularly apt models for populations containing cells in different stages of development or species in different stages of evolution. A good example is given by the distributions obtained in **T cell subset analysis** of cells from thymus and peripheral blood, as illustrated in Figure 5-11 (p. 241). The relative numbers of helper/inducer and cytotoxic/suppressor T lymphocytes are determined using monoclonal antibodies directed against the CD4 antigen to identify the first of these cell types and antibodies directed against the CD8 antigen to identify the second<sup>318,321-2</sup>; both

types also bear the CD3 antigen. Cell populations are illustrated in 3-dimensional “cloud” plots.

The plot on the right of Figure 5-11, representing cells taken from the blood, shows clear “antibody positive” and “antibody negative” populations; there are some dual positives, but few, if any, cells with intermediate fluorescence values. I claim that this pattern alone should tell us that **the CD4 and CD8 antigens emerge on cells during a developmental phase occurring outside the bloodstream.** Now how in blazes, you may ask, are we supposed to know that? Simple, I reply. It follows from:

*Shapiro's Fourth Law of Flow Cytometry  
(The Supermarket Theorem):*

*Most babies aren't born in supermarkets.*

If you walk around a supermarket, you will see many women with children, some with infants and some with older children, and you will see many women without children, a few of whom look as if they are about to change their status at any moment. However, I certainly have never seen a baby born in the considerable time I have spent in supermarkets, and you probably haven't witnessed such a blessed event either. Since we both know where babies come from, we are forced to conclude that arrangements are usually made for them to be born in someplace other than a supermarket.

Now, to find out where T cells come from, we go not to Masters and Johnson, but to Reinherz and Schlossman<sup>322</sup>, who, with others, have shown that the inducer T cells, which bear the CD4 but not the CD8 antigen, and the cytotoxic/suppressor T cells, which bear CD8 but not CD4, develop in the thymus, and that early and immature thymocytes bear neither the CD4 nor the CD8 antigen, while immature thymocytes bear both CD4 and CD8 and lose one or the other as they mature. If we look at a population of cells from the thymus, shown on the left side of Figure 5-11, we see a distribution in which, while there are areas of higher and lower cell density, there are continuous ranges of both CD4 and CD8 antigen expression. If it reminds you as much of a sliced ginger root as it does me, you're entitled to take a sushi break at this point.

The thymic cells with fluorescence values intermediate between those of the “positive” and “negative” clusters in the distribution from blood on the right side of the figure represent those cells that are acquiring and losing antigen. In the second edition of this book, not having either the data or the software needed to produce Figure 5-11, I constructed a simulated version of the distribution from 3-color fluorescence data published by Lanier, Allison, and Phillips<sup>787</sup> to illustrate the same point; I was relieved to find that it looked pretty much like the real distribution shown in the figure.

Since the processes of acquisition and loss of antigen during maturation do not occur instantaneously by quantum leaps, we would expect to find cells in all stages of maturation present in the tissue compartment (the thymus

in this example) in which maturation occurs. Conversely, and more generally, if a sample of cells from a particular tissue compartment (the peripheral blood in this example) contains clearly distinguishable populations of cells bearing and lacking an antigen, and few cells which bear very little antigen, the acquisition and loss of the antigen in question must either occur outside the compartment from which the sample was taken, or be **rare events** in that compartment, like babies being born in a supermarket. The ginger root doesn't have the same density everywhere; it is thinner, or less dense, in the areas that represent rare events.

Figures 3-10 (p. 97) and 7-16 (p. 321), which depict DNA and RNA content in stimulated lymphocytes, illustrate a situation in which a rapid transition makes what should be a continuous distribution appear to contain discrete clusters. About 20 hours after exposure to mitogens, resting lymphocytes, which normally contain only small amounts of RNA, begin to make the larger amounts necessary for their subsequent multiplication. However, when you look at the distribution, there are a lot of resting ( $G_0$  or  $G_{1Q}$ ) cells, containing little RNA, and a lot of  $G_1$  cells, containing noticeably more RNA, and few, if any, cells in between. Since we know that the transition from  $G_0$  to  $G_1$  takes place in the compartment (in this case, the culture vessel) from which the sample is taken, we have to conclude that cells don't take very long to gear up for RNA synthesis, or, in other words, that they don't stay in the transitional, or  $G_{1T}$ , state, for very long; if they did, we would expect to find a continuum of  $G_{1T}$  cells between the  $G_0$  and  $G_1$  clusters.

The evolutionary biologists had a similar problem for over a century after Darwin published his *Origin of Species*. When fossils were collected from sites in which different species had presumably evolved, the expected “missing links” between species were generally absent. This becomes readily understandable in terms of the theory of evolution in punctuated equilibria proposed in 1972 by Niles Eldredge and Stephen Jay Gould, according to which most evolutionary change occurs in brief bursts, resulting in the intermediary forms not being around very long. Finding one would, then, be expected to be a rare event.

In the absence of rare events generated by short-lived transitional states, the multidimensional distributions we get when we look at maturing cell populations in the environments in which they mature, no matter which parameters we look at, will contain continuously connected “ginger root” blobs rather than discrete clusters; unsupervised algorithms and expert systems can find clusters, but how you slice your ginger roots is a matter of taste. This can be restated as:

*Shapiro's Fifth Law of Flow Cytometry  
(The Barber Shop Theorem):*

*No man walks into a barber shop with a long beard who hasn't had a shorter one, and no barber can make a beard a lot shorter without cutting it.*

Hair doesn't grow in quantum leaps, and as is the case with the ginger root, how you cut it is also a matter of taste.

The Barber Shop Theorem has some other practical applications in hematology, for example, in distinguishing between immature reticulocytes and mature red blood cells. Reticulocytes are identified by their content of RNA, which is lost within a day or so of the time these cells enter the blood from the marrow; the distribution of RNA in red cells is therefore continuous. To duplicate the reticulocyte count as performed by a human observer, you have to find some arbitrary point in the distribution at which to apply a razor.

As neutrophil granulocytes mature, they, like erythrocytes, have less and less use for their nuclei, but instead of turning the poor old things out in the cold, they let them have the spare room, in which the nuclei become progressively gnarled with age. The nuclei of mature granulocytes have several lobes connected by threads of chromatin; less mature "band" cells have nuclei that are twisted around in the fashion of crullers, but not really lobulated. Why and how do you tell the difference between the immature "bands" and the mature cells with segmented nuclei ("segs")? To answer the "why" first, finding an increase in the proportion of immature cells indicates that the bone marrow is responding to stress due to inflammation, infection, etc., so knowing the numbers and fractions of bands and segs is helpful in diagnosis. How? To coin a paraphrase, I don't know much about hematology, but I know what I like. Well, it's actually a little more precise than art criticism, but, again, it's an arbitrary distinction at its base because the process of nuclear involution is a continuous one. Nuclear morphology being kind of tough to assess in the average flow cytometer, various people have looked for various flow cytometric methods of telling bands from segs, because you need to be able to do it if you want to sell flow cytometric differential counters to a lot of clinical laboratories. My former colleagues and I ended up using the size distribution of the neutrophils; the immature cells are larger, and what you end up doing is applying the razor to a continuous distribution. Nonetheless, by cutting in the right place, we could get good band/seg ratios, just as one can and does get reasonable reticulocyte counts from RNA content distributions.

Back in 1980 or so, when everybody in the diagnostics business was mesmerized by monoclonals, the folks at Ortho decided to try their hand at distinguishing reticulocytes from mature erythrocytes<sup>324,764</sup>, and at differentiating between bands and segs<sup>325</sup>, using monoclonal antibodies. Did it work? Yes and no. Yes, you could produce distributions of antibody fluorescence which you could slice as other distributions are sliced to get a retic count or a band/seg ratio. And no, Virginia, they didn't find a surface antigen present on reticulocytes and absent on mature erythrocytes, or one present on bands and absent on segs, and I doubt that anyone else ever will.

When monoclonal antibodies were still a new technology, a lot of people had the idea that there would turn out to be a single surface antigen to identify each different cell type

in the body. Experience has taught us that this is probably not the case. Surface antigens are not Nature's version of bar code; many of them have defined receptor functions and we can expect some function to be defined for most of the rest, because it's unlikely that structures that seem to be fairly well conserved during evolution serve a purely decorative purpose. This brings me to:

*Shapiro's Sixth Law of Flow Cytometry:  
There are some cell identification problems that  
even monoclonal antibodies can't solve.*

Shave, if you must, but try to avoid splitting hairs.

### Practical Multiparameter Gating: Color Wars

The most sophisticated current applications of flow cytometry involve the definition of clusters, or of nodes of ginger roots, in multidimensional spaces. This is often accomplished by defining a bitmap gate on the two-parameter display in which a particular cluster or node is best separated from other clusters or nodes. A color is assigned to each gate, making it possible to find the location of cells in any cluster on any two-parameter display by plotting cells falling within the gate in the assigned color. The procedure is illustrated in the color figures on the back cover showing normal and leukemic bone marrow; these were provided for the previous edition of this book by Leon Terstappen, then at B-D. The figures were generated using B-D's Paint-a-Gate™ software; other manufacturers and third party developers have analogous programs.

In the late 1980's and early 1990's, the application of multiparameter flow cytometry to determining patterns of differentiation of myeloid leukocytes in normal and leukemic human bone marrow<sup>1154,1212,1498,1760-71</sup> represented the highest level of sophistication of the technology.

The multiparameter approach to cell differentiation in marrow was pioneered by Loken and Civin<sup>990,1755-9</sup> and their collaborators, who originally studied erythroid and B cell development, bringing B-D's resources in the areas of instruments, reagents, and software to bear on the problem. The work on phenotyping of myeloid leukemia, continued by Terstappen and his colleagues, epitomized the intelligent application of sophisticated cytometric methods to a clinical problem.

The figure depicting normal adult bone marrow shows the location of early leukocyte precursors, identifiable by their CD34 surface antigen, in a two dimensional display of forward (FLS) vs. polynomially transformed<sup>1727</sup> (ICLS) side scatter values, and in two-parameter displays showing expression of CD34, CD11b, and CD15. This pattern is consistently observed in normal marrow, which shows surprisingly little variation from individual to individual. The trajectories along which normal cells move as they mature, indicated by arrows on Panels A and C, were determined by examining cells sorted from various regions of the displays.

The analogous displays depicting bone marrow cells from a patient with acute myelocytic leukemia (AML) are

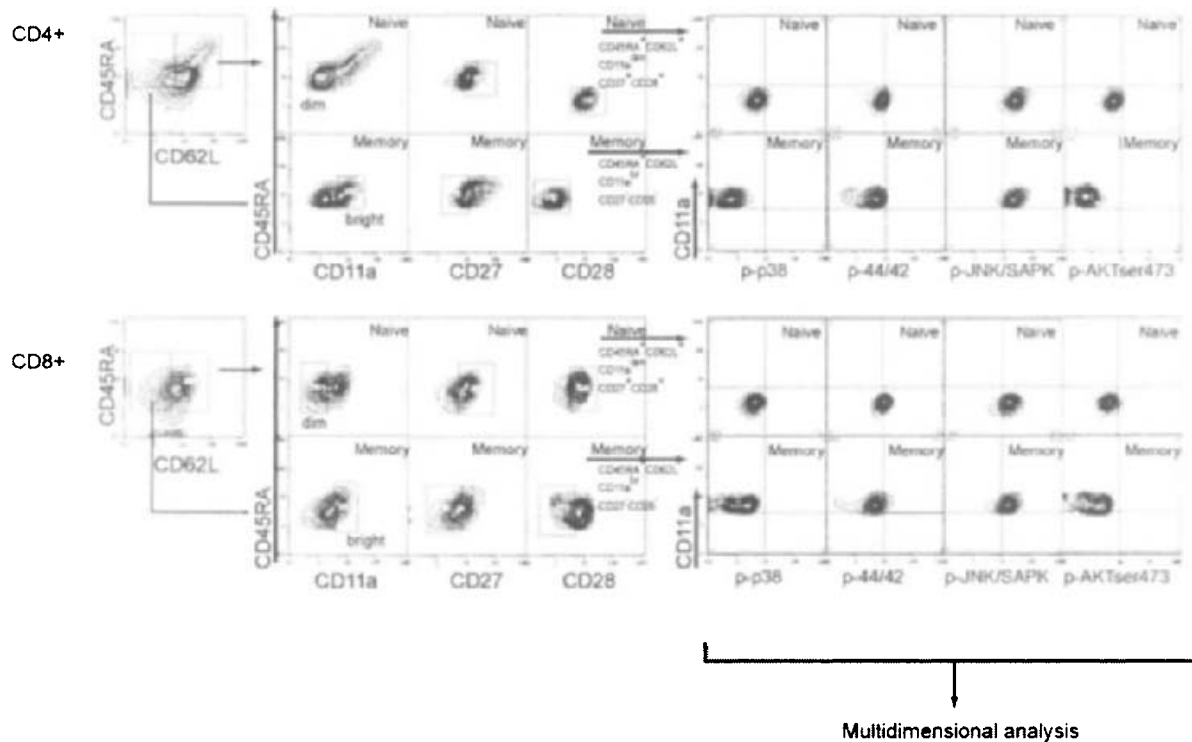

Figure 10-9. Subsetting of human T-cells into truly naive and memory classes and measurement of activated signaling kinases using 11-color fluorescence flow cytometry. Resting T-cells were prepared by density gradient centrifugation with other cells removed by adherence and magnetic separation, with purity assessed by measurement of forward and side scatter and CD3 antibody binding. From: Perez OD, Nolan GP: *Nature Biotechnology* 20:155-162, 2002 (reference 3000), © 2002 Nature Publishing Group; used by permission.

quite different. They are characterized by the appearance of leukemic cells in regions in which few or no cells appear in displays from normal marrow. As a group, however, leukemic patients are extremely heterogeneous; there are always cells where there shouldn't be cells, but no two leukemic patients show exactly the same pattern.

Interestingly enough, when my colleagues at Block and I<sup>989</sup> ran samples from patients with acute leukemia through the prototype differential counter system, without benefit of monoclonal antibodies, we also noted that leukemic cells showed up where there weren't normal cells, and that, while normal cells from different people showed up in pretty much the same places on displays, no two leukemic bloods looked alike. It may be more important to have a multi-parameter measurement space, which we did have, than to have monoclonal antibodies or equivalently specific reagents. As I recall, some people from Technicon presented some data years ago on analyses of cells from patients with acute myelocytic leukemia using the peroxidase and esterase channels in their Hemalog D blood cell counter, and they found pretty much the same patterns we did, i.e., normals looked pretty much alike, and leukemias were different, and varied.

Verwer and Terstappen<sup>1212</sup> developed a computer procedure for automatic assessment of lineages of leukemias and Frankel et al<sup>1215,1217</sup> applied neural network methods to analysis of normal and leukemic marrow. Manual and automated

multiparameter analysis make it possible to detect very small numbers of leukemic cells (between 1 in  $10^3$  and 1 in  $10^6$  cells) in marrow following the induction of clinical remission by combination chemotherapy, which falls under the rubric of **rare event analysis**, whether you are printing in color or black and white. I'll continue the story of leukemia phenotyping later on.

These days, complex gating strategies are more dependent on the number of colors you can measure than on the number of colors you can display. The state of the art in 1994, when the previous edition appeared, was 5-color fluorescence measurement<sup>1306</sup>; in the years since, colors have been added at the rate of about one a year, largely through the efforts of a large and creative group of people in the Herzenberg lab at Stanford<sup>2497,2629,2644,2995,3000,3</sup>.

I can't think of a better illustration of the current (published) state of the art – 11 fluorescence colors plus forward and side scatter – than Figure 10-9, taken from a 2002 paper by Perez and Nolan<sup>3000</sup>, for which the data were collected in the Herzenberg lab. The paper described the measurement of activated signaling kinases in human T cells separated by multiparameter gating into sub-subsets of truly naive ( $CD45RA^dim CD62L^dim CD11a^{dim} CD27^+ CD28^+$ ) and memory ( $CD45RA^{bright} CD62L^{bright} CD11a^{bright} CD27^+ CD28^+$ ) cells<sup>2995, 8, 3000, 1</sup>. The input cell population of resting T cells was prepared and purified from peripheral blood by Ficoll-paque density

gradient separation, followed by depletion of adherent cells and immunomagnetic separation using antibodies to CD14, CD16, CD19, CD44, and HLA-DR to remove macrophages, NK cells, B cells, and activated T cells. Cells were then stained with antibodies to CD4 (PE-Cy5.5), CD8 (Cascade Yellow), CD45RA (APC-Cy7), CD62L (PE-Cy7), CD11a (Cascade Blue), CD27 (Alexa 594), and CD28 (APC-Cy5.5), and with antibodies to phosphorylated or nonphosphorylated forms of one or more kinases. Antibodies to kinases were also, on occasion, labeled with fluorescein, PE, and APC, and, on occasion, with Alexa 488, Alexa 546, Alexa 568, Alexa 594, Alexa 633, Alexa 660, or Alexa 680. Discrimination between naive and memory cells reveals some differences in kinase activity between resting naive and memory cells; additional differences are noted when cells in different subsets are stimulated by kinase-activating agents (see the paper<sup>3000</sup> for details).

### Finding Rare Cells

Flow cytometry has been applied, with varying degrees of success, to finding cell types that are present in samples at very low frequencies. How effectively this can be done is a function of how readily these rare events can be identified. I have already touched on some qualitative and quantitative aspects of **rare event analysis** and rare event sorting on pp. 19-20, 42, 178-80, 269, and 352.

If you look at rare event detection as basically a statistical problem, what you need to do is distinguish between samples from two distributions with different means. Whether or not such a distinction is possible, however, depends on the variances of the distributions as well as on the means.

#### One Parameter is Not Enough

Suppose, for example, you are trying to use a single-parameter immunofluorescence measurement to find rare positive cells among a population of negative cells. Let's say the positive cells have a mean fluorescence signal at channel 40, with a 30 percent coefficient of variation (CV), while the negative cells have a mean fluorescence signal at channel 20, also with a 30 percent CV; disregarding reality for now, we will assume linear scales and normal or Gaussian distributions.

The CV is equal to the standard deviation (S.D.) divided by the mean; S.D. for the positive cells is therefore 12 channels, and S.D. for the negative cells is 6 channels. Based on tables of the normal distribution and its integral (p. 234), about two-thirds of the positive cells will be found between channels 28 and 52, with half of them lying below channel 40, while almost 10 percent of the negative cells will be found between channels 28 and 52, although only about 13 negative cells in 10,000 should lie above channel 38. These numbers make it unlikely that positive cells present in a ratio of less than 1 per 1,000 negative cells can reliably be detected by single parameter measurements.

Now suppose we're looking at DNA content, and we want to find rare abnormal hypodiploid tumor cells (mean

fluorescence at channel 20) among normal diploid cells (mean fluorescence channel 40). Thus, we're dealing with the same difference between population means we had in the last case. Let's use a realistic CV of 5 percent for the DNA measurements, and neglect S, G<sub>2</sub>, and M phase cells for the moment. 99.8 percent of the abnormal cells will lie between channels 17 and 23; 99.9999 percent of the normal cells will lie above channel 30. Just going by the numbers, we could easily detect one hypodiploid cell per 10<sup>6</sup> normal cells.

In case you haven't noticed, though, I threw in a ringer in the DNA content example. In the real world, we are probably more likely go looking for tetraploid than for hypodiploid abnormal cells. So let's say we've got the normals at channel 20 and the abnormal cells at channel 40. Now, even if there are no S, G<sub>2</sub>, or M phase cells in either population, if we only look at DNA content, without some way of telling doublets from single cells, we're going to get a substantial number of counts in the neighborhood of channel 40 resulting from two normal cells passing through the system together, either by virtue of being physically attached or by virtue of being in very close proximity as they go by the observation point. We can use some established tricks, such as comparing peak vs. integral of fluorescence signal or looking at scatter or extinction pulse width vs. fluorescence, to discriminate single abnormal cells from doublets, but, unless we go to a 3-D slit scanning system and/or sort all of our suspicious cells onto slides, we are very unlikely to be able to pick out one abnormal cell in a million normals.

Moving closer to the real world, and keeping the same 5% CV's, we'd think we'd be better off with abnormal cells at channel 30 and normals at channel 40 than with either abnormal cells at channel 40 and normals at channel 30, or abnormal cells at channel 40 and normals at channel 20. We already know that the last of these scenarios gets us into problems with doublets; the middle one will be troublesome if there are any normal S phase cells, because some of these can be expected to lie at channel 40 and, if the fraction of abnormal cells is too small to form a recognizable peak, we have no way to spot the abnormal cells. In theory, we may have doublets and S phase cells, but we shouldn't have 3/4 of a cell or nucleus going through, so we should readily spot the abnormal cells at channel 30 if the normals are at channel 40. We should, as long as there is no debris in the sample; in the real world, particularly when you go hunting for DNA aneuploidy in preps from solid tumors, you may have trouble finding nuclei but you can have all the debris you don't want. Well, fine, suppose you use a mathematical model to subtract out the debris distribution? No, that won't work either, because the model is only an approximation, and you're still going to need a substantial fraction – say 5 percent or more – of abnormal cells to be sure of finding them.

So far, then, having considered detection of rare cells using single-parameter measurements, we have discovered that we can tell from the numbers when there's no chance of our finding rare cells, but, also, that, when the numbers tell us there is a chance, factors other than statistics may prevent us

from finding the rare cells. Does rare cell detection get any easier when we use multiparameter measurements? Would I ask if it didn't?

If we go back to the leukocyte differential counting procedure discussed on pp. 248-50, it becomes fairly obvious that multiparameter analysis improves things. That procedure started with a data file of 1595 leukocytes, obtained by gated analysis of whole blood, without red cell lysis, using nuclear fluorescence as the gating parameter. So, to count 1595 leukocytes, we also had to count about 1.5 million red cells and a few hundred thousand platelets, and we managed to pick out the leukocytes, which represented only about 0.1 percent of the total population analyzed, almost flawlessly (we decided after further analysis, that 6 of our 1595 objects weren't leukocytes after all). But it gets better. In the first step of breaking the leukocyte population into subpopulations, we manage to pick out the eosinophils, one of the less common leukocyte types; there were 102 of them, roughly 6 percent of the leukocytes and thus roughly 6 per  $10^7$  of the original cell population.

Ah, but that's not a fair test, you say, because the eosinophil stain was very bright and very specific. Objection sustained, but I'm ready for you. Let's look at the basophils, the rarest of the leukocytes. They were not picked out by using a specific stain for their IgE receptors or their glycosaminoglycans; instead, they were identified because the cluster in which they fell based on nuclear fluorescence, forward and right angle scatter, and extinction measurements lay far enough away from the other cell clusters to let us find them by blind luck. The hardest part of our job in identifying the basophils when the differential counting procedure was developed lay in finding a sample with 5 percent basophils, so we could be sure that the cluster was what we thought it was. Among 1595 (or 1589, if you really want to get picky) leukocytes, we identified 11 basophils, or about 7 cells per  $10^6$  cells in the original population. That suggested to me that multiparameter analysis, even using parameters that didn't seem to be all that specific for discrimination, was the most practical way to go when looking for rare events.

### Cocktail Staining Can Help

This approach (p. 352) is often useful in rare cell detection problems involving immunofluorescence measurements. Ryan et al.<sup>883</sup> considered the problem of detecting minimal residual disease in acute lymphoblastic leukemia based on finding and counting cells bearing the common acute lymphoblastic leukemia antigen (CALLA or CD10). They stained cells with a fluorescein-labeled anti-CALLA antibody combined with a "cocktail" of various phycoerythrin-labeled antibodies binding to different types of mature leukocytes, and performed analyses gated on forward and orthogonal scatter and phycoerythrin fluorescence to include only those mononuclear cells not stained by the phycoerythrin-labeled antibodies. This scheme allowed detection of CALLA-positive lymphoblasts at levels of 1 cell per  $10^5$  peripheral blood mononuclear cells, representing an

improvement in sensitivity of better than a hundredfold over single-parameter immunofluorescence measurements.

### Dirt, Noise, and Rare Event Detection

Gross et al.<sup>150,2331</sup> were able to reliably detect rare cells at frequencies as low as 1 in  $10^6$  by combining cocktail staining with a rigorous cleaning procedure for the flow system, which minimized sample carryover (see pp. 178-80), and a processing technique which excluded "bursts" of data likely to represent system noise and or debris, rather than cells, in the sample. Rare cell detection at this level is likely to be necessary in identifying fetal cells in maternal blood, or residual solid tumor cells, e.g., breast cancer cells, in bone marrow.

### Really, Really Rare Events: Alternatives to Flow

When we start getting down to cells which represent 1 in  $10^7$  cells in the sample, we run across a new problem, which is fundamental to the flow cytometric method. If we count 10,000 cells/s, which is faster than a lot of us run routine analyses, we can run for an hour and find four of the cells we're looking for. To really be sure we're seeing them, we might want to count a few dozen, and that's a day's work. Unless we're talking about red cell variants, that's also a large total number of cells to have to take out of a patient.

Provided we have a way of staining the cells we're looking for intensely enough so that it's easy to find them, we may be better off using a static system like a wide-field microscope, and just counting the positive cells, rather than tying up a flow cytometer for days on end. This is certainly true when we're trying to do something else with very rare cells when we do find them, e.g., genetic analysis by *in situ* hybridization; using modern imaging and static systems, with computer-controlled stages and scanners, it is relatively simple, once a cell has been located, to find it again after the slide has been removed, processed, and replaced.

The **Automated Cellular Imaging System (ACIS)**<sup>3004,5</sup>, from **Chromavision**, uses immunoenzyme staining and automated analysis of bright field microscope images to identify malignant cells in marrow at frequencies as low as 1 cell in 100 million, although an immunomagnetic enrichment step may be necessary to reach this detection level.

The **CellTracks**<sup>TM 2385,3006-9</sup>, under development by **Immunicon**, features a small but capable scanning laser cytometer, with optical and mechanical components largely derived from CD player parts, that uses as many as three laser beams for measurement of fluorescently and immunomagnetically labeled cells drawn by a magnetic field to the viewing surface of a disposable sample container. Immunicon has developed other immunomagnetic separation technology that has been used to enrich samples for residual tumor cells and other rare cell types prior to analysis using either flow or scanning cytometry<sup>3010-3</sup>.

**Oncosis's Photosis**<sup>TM 3014</sup> is designed to scan a 250 cm<sup>2</sup> chamber containing as many as 500 million cells in a clinical specimen intended for stem cell transplantation,

identify any non-Hodgkins lymphoma cells present, and destroy the tumor cells by “zapping” them with a pulsed laser beam. **Cyntellect**, a spinoff from Oncosis, offers the **LEAP™**<sup>3015</sup> research platform for high throughput cell image analysis and manipulation.

## 10.4 TRICKS AND TWISTS: ODD JOBS FOR FLOW CYTOMETRY

### Single Molecule Detection

The detection of single fluorescent molecules bearing multiple chromophores was proposed, and achieved using a static system, by Tomas Hirschfeld in the mid-1970's<sup>884,5</sup>, when he was at Block Engineering. Mike Hercher, also at Block, then built a high-sensitivity flow cytometer<sup>94</sup> designed to perform assays for viral antigen based on the detection of small numbers of multiply labeled antibody molecules bound to a single virus particle. This was the apparatus used to measure the scatter signal distribution from bacteriophages shown in Figure 7-5 (p. 288); its fluorescence sensitivity was calculated to be sufficient for detection of 36 molecules of fluorescein, a number I hesitated to put in print until other people got into the same ballpark. When the original work with this apparatus was done, neither monoclonal antibodies nor phycobiliprotein labels were available; the use of both of these types of reagents would obviously make single-virus detection based on this approach easier, although factors other than instrument sensitivity influence feasibility.

Work on flow cytometric detection of small numbers of molecules continued at Los Alamos, where Dovichi et al<sup>886-7</sup> achieved sensitivities comparable to that of the Block apparatus<sup>94</sup> for detection of fluorescein and rhodamine dyes, and at Berkeley and Stanford, where Mathies and Stryer<sup>888</sup> established the feasibility of detecting single molecules of phycoerythrin. Such detection was actually achieved in 1987 by Nguyen et al at Los Alamos<sup>60</sup>, using a slow flow system with a single photon counting detector.

While single molecule detection in flow systems represents an impressive achievement, flow cytometry is not the only technology, and is not necessarily either the most sensitive or the most efficient technology, for making fluorescence measurements at this level of sensitivity. Before the First Edition of this book was published, Coleman et al<sup>260</sup> had visualized DNA in individual DAPI-stained virions (and, I was told, in plasmids) by fluorescence microscopy and quantified it by microphotometry, using a photometer based on a Zeiss fluorescence microscope with a 100 W Hg arc lamp source. The single molecule detection limit for DAPI-stained DNA had also been attained by Morikawa and Yanagida<sup>576</sup> using video microscopy. Later, in preliminary experiments (A. Coleman and M. Block, personal communication), Coleman's microphotometer was used to detect bacteriophages based on the spatial coincidence of fluorescence signals from stained DNA and fluorescent antibodies.

Since, in many potential applications of high-sensitivity cytometry, e.g., virus detection in clinical specimens, the objects to be detected are not only of near-molecular dimensions but may be present at very low concentrations (< 10<sup>4</sup> particles/ml), detection in a flow system involves spending a lot of time running portions of the sample through the system which do not contain the objects of interest. In such cases, it is almost essential to concentrate the raw sample to increase throughput; it becomes logical to concentrate it to the point at which the analyte can be looked for on a slide in a static system. However, maximizing detection sensitivity in static or scanning systems requires that the illuminated region be made as small as possible.

**Near-field optical microscopes**, in which optical fibers of extremely small size (10 nm) are used to bring light to the specimen, allow selective illumination of regions approaching molecular dimensions, permitting not only the detection of single fluorescent molecules, but their characterization, e.g., by fluorescence lifetime. The Los Alamos group investigated this technology<sup>1819</sup>. However, in recent years, impressive spatial resolution in fluorescence microscopy has been achieved using conventional (far-field) optics, if not conventional illumination.

**Stimulated Emission Depletion (STED) microscopy**, described in a 2002 report by Dyba and Hell<sup>3016</sup>, decreases the size of a detected fluorescent spot by quenching the excited molecules at the rim. Quenching is accomplished by stimulated emission. Two synchronized trains of laser pulses are used; the first pulse excites the fluorophores in the focal region, and a following red-shifted pulse, in a “donut” mode, quenches molecules at the rim of the focal spot, leaving fluorescence from the center largely unaffected. Using 760 nm excitation, Dyba and Hell achieved an effective spatial resolution of 33 nm, or 1/23 wavelength; they have been able to apply their technique to high-resolution imaging of structures in living cells and bacteria.

Single molecule detection has also been achieved, with less fanfare, in lower-tech, lower-budget apparatus. On p. 132, I noted that Unger et al<sup>2446</sup> were able to detect fluorescence of single molecules of tetramethylrhodamine-conjugated protein using a (relatively inexpensive) cooled CCD camera and a fluorescence microscope illuminated by a 100 W Hg arc lamp. Chiu et al<sup>3017</sup> used the same apparatus to develop a calibration procedure for quantitative measurements of GFP down to the single molecule level.

### DNA Sizing, if not Sequencing, in Flow

In 1993, Goodwin et al, at Los Alamos, reported the use of a slow flow system, TOTO-1, and single photon counting to size DNA fragments as small as 5 kilobase pairs.

The Los Alamos group proposed the use of their methodology for **DNA sequencing**; a DNA fragment would be attached to a bead fixed in position upstream, and single molecules of the fluorescently labeled end base would be detected downstream after enzymatic cleavage. This hasn't happened yet, but the DNA sizing work has continued.

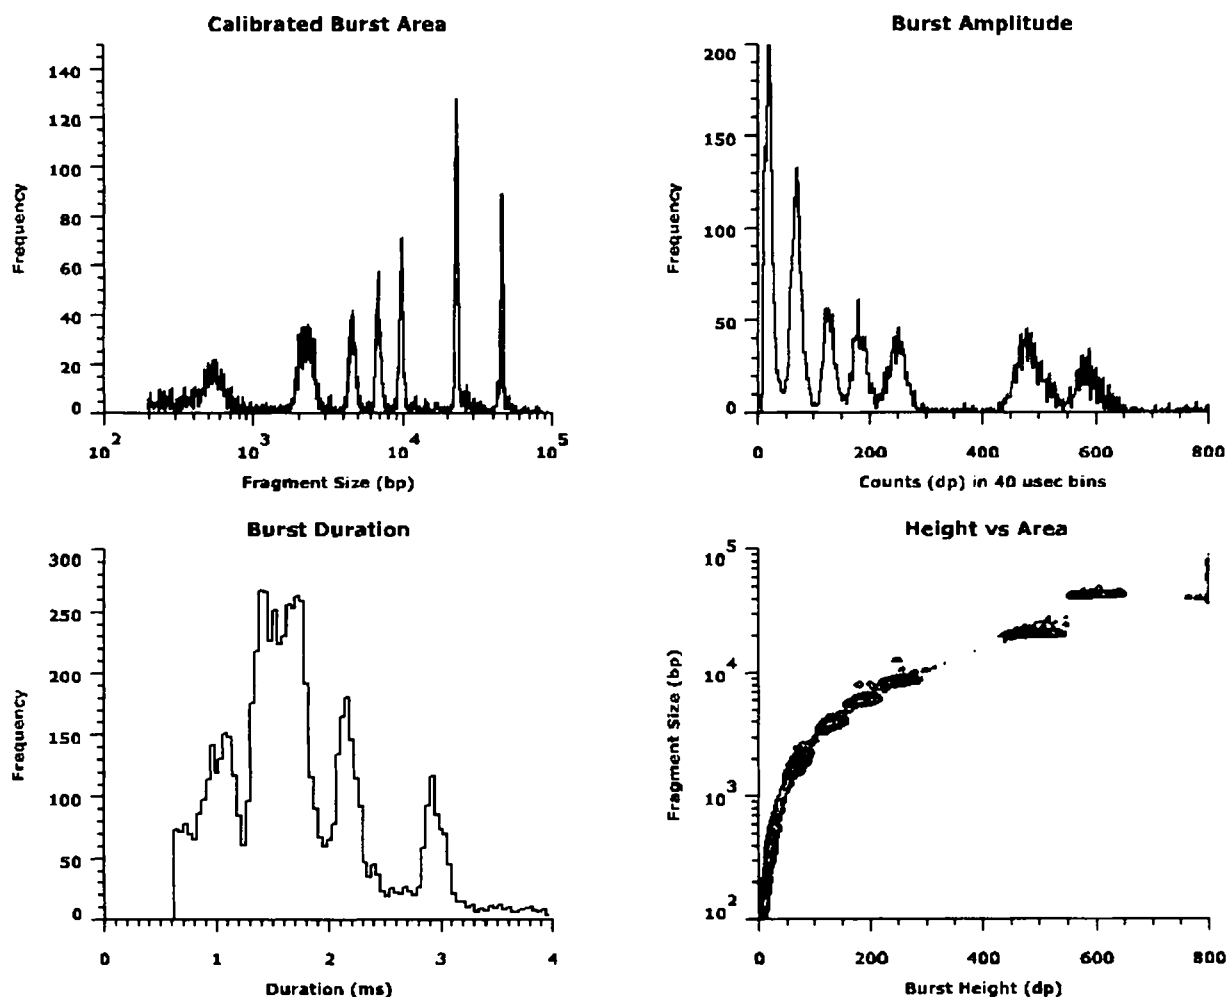

Figure 10-10. Analysis of bacteriophage lambda DNA and a *Hind* III digest of lambda DNA in a slow flow system. Courtesy of Rob Habbersett, Los Alamos National Laboratory.

Rob Habbersett, at Los Alamos, has reduced the DNA sizing apparatus to a small, benchtop system using 0.5 mW of 532 nm illumination from a YAG laser; samples flowing at 1 cm/sec are examined in a quartz cuvette with a 250  $\mu\text{m}^2$  flow channel, and fluorescence at 555-595 nm from SYTOX Orange (Molecular Probes)<sup>1334</sup> is collected using a 3.1 mm, 0.68 N.A. aspheric lens. A Perkin-Elmer single photon counting APD module is used as the detector, and data are processed by a multichannel scaling PC plug-in board that counts detector pulses in intervals ranging from 4 to 50  $\mu\text{s}$ .

Figure 10-10 illustrates the result of analyzing a mix of DNA fragments from a restriction digest of bacteriophage lambda DNA, with a small amount of intact lambda DNA added. A total of 7800 individual fragments are represented. *Hind* III digestion produces 8 fragments from each completely cut lambda DNA molecule, with fragment lengths of 125, 564, 2027, 2322, 4361, 6557, 9416, and 23130 base pairs (bp). The 125 bp fragment was not detected in this example, and the two fragments at 2027 and 2322 bp (2<sup>nd</sup>

peak from the left in the burst area histogram) are not separately resolved. Each individual detected event (i.e., fragment) comprises a "burst" of detected photons; the data processing software extracts the area, maximum amplitude, and duration of each burst, and stores them as list-mode parameters, from which all displays are generated. The burst-area scale was calibrated in terms of fragment length by fitting a Gaussian to each peak to find the center of the peak and performing a linear regression against the known fragment lengths.

While burst area is proportional to fragment size, burst amplitude, analogous to peak height, is not. The contour plot of amplitude vs. fragment length shows that, as fragment length increases, both amplitude and area increase until the fragment length is about 36 kbp. In the flow cell, the hydrodynamic forces extend the fragments as they accelerate off the end of the injector tip, and pass through the laser beam, which is focused to a spot approximately 11  $\mu\text{m}$  in diameter. A 36 kbp fragment is long enough to fill the

entire spot, placing a nominal maximum number of dye molecules in the probe volume and therefore [nearly] maximizing burst amplitude. Larger molecules extend to longer lengths (a fully extended 48.5 kbp lambda DNA molecule, for example, is roughly 16  $\mu\text{m}$  long), and, while they produce only slightly higher burst amplitudes, they have substantially longer burst durations and larger burst areas. Circular DNA constructs (e.g. plasmids) or molecules that are kinked, looped and not fully extended in flow can produce higher amplitude bursts.

DNA fragment sizing apparatus has been built at the University of Twente<sup>2440,2452</sup> and at CalTech (a microfluidic system)<sup>2356</sup> as well as at Los Alamos. For a time, it appeared as if flow cytometric DNA fragment sizing would be competitive with agarose gel electrophoresis; the flow method is faster, uses a smaller sample, and produces results on a linear scale. The picture has become somewhat clouded with the appearance of microfluidic capillary electrophoresis apparatus for DNA sizing, which also has speed and sample size advantages when compared to conventional gel electrophoresis. Of late, the Los Alamos group has advocated the use of DNA fragment sizing for rapid identification of bacterial pathogens<sup>3018,20</sup>; this is likely to attract more attention after the U.S. national experience with anthrax in 2001 than it might have before.

### Solid Phase (Bead) Assays Using Flow Cytometry

By the 1980's, people at Los Alamos and elsewhere had become aware that flow cytometry might offer some advantages as a detection method for fluorescence immunoassays. Saunders, Martin, and Jetz<sup>1019</sup> described a competitive binding assay in which fluorescently tagged antigen competed with an antigen analyte for binding sites on nonfluorescent, antibody-coated beads. Elsewhere, McHugh et al<sup>1820</sup> developed a sandwich assay for circulating immune complexes, in which the analyte was bound to beads coated with the complement component C1q, and rendered detectable by the addition of fluorescent anti-immunoglobulin antibodies.

Saunders et al<sup>1834</sup> developed a solid phase flow cytometric assay for the DNA-binding antibiotic actinomycin D, using mithramycin, which becomes fluorescent on binding to DNA, to compete with the analyte, which does not, for sites on DNA-coated spheres.

Flow cytometers can also be used to detect antigen-antibody reactions without making fluorescence measurements, for example, by using scatter or extinction signals to detect aggregation of small antigen-coated particles by soluble antibody. Sykulev, Cohen, and Eisen<sup>1855,6</sup> adapted this technique to determine the equilibrium constants of antigen-antibody reactions by examining the effects of addition of competing soluble antigen; they reported that this technique is usable with almost any soluble antigen and with antibodies exhibiting a very wide range of equilibrium constants.

By the time the previous edition of this book appeared, variations on the basic theme included assays for serum anti-

bodies, employing antigen-coated beads and fluorescent anti-immunoglobulins<sup>1821-6</sup>, sandwich assays for antigens, using antibody-coated beads and fluorescent antibodies<sup>1827, 30</sup>, and the use of small (0.1  $\mu\text{m}$ ), antibody-coated fluorescent beads instead of fluorescent antibodies to detect antigen bound to nonfluorescent beads coated with unlabeled antibody<sup>1831</sup>.

Flow cytometric bead immunoassays are said to be equal to or better than conventional enzyme immunoassays in terms of sensitivity, specificity, and dynamic range; their major drawback to date is the requirement of a relatively expensive instrument for readout. Lindmo et al<sup>1832</sup> reported that the dynamic range of sandwich flow cytometric assays for antigens could be extended (from 2 decades to 3 decades) by employing two different sizes of particles coated with antibodies of substantially different affinities; Frengen et al<sup>1833</sup> considered ways of minimizing serum interference with flow cytometric solid phase assays.

### Cocktails for 100: Multiplexed Bead Assays

Flow cytometric bead assays have now made it into the mainstream thanks to use of multiplexing schemes that permit separate analyses of a large number of ligands to be performed in a single aliquot of sample.<sup>2370-5,3021</sup>

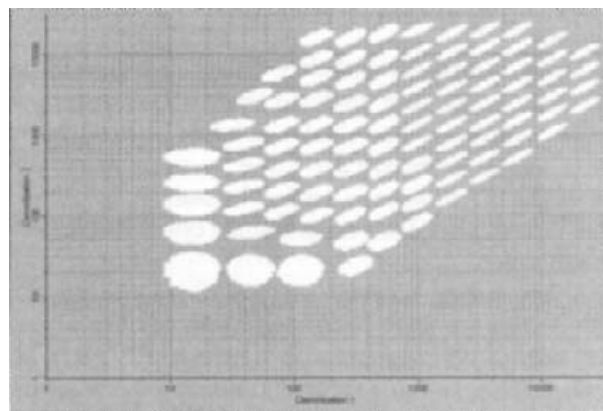

Figure 10-11. Positions of clusters representing 100 different color-coded beads used with the Luminex 100™ system for chemical analysis. The horizontal and vertical axes, respectively, indicate intensities of 635→658 and 635→710 nm fluorescence. Courtesy of Luminex Corporation.

The Model 100 flow cytometer made by Luminex (Chapter 8) can perform as many as 100 ligand-binding assays per tube. Beads approximately 5.5  $\mu\text{m}$  in diameter are color-coded with unique mixtures of two red-excited dyes; because large numbers of molecules of these dyes can be bound to beads, they provide strong signals, and fall into well-delineated clusters on the "bead map" illustrated in Figure 10-11 above.

A different color code is used for each analyte to be assayed; analyte is captured by an appropriate reagent (antibody, gene probe, etc.) bound to the bead, and detected by a

“reporter” reagent labeled with phycoerythrin or another green-excited, yellow fluorescent label such as Cy3.

A mixture of beads appropriate for the desired measurements is mixed with a single aliquot of sample in a tube or in one well of a 96-well plate; the sample-bead mixture is then incubated with a mixture of all of the reporter reagents, and introduced into the flow cytometer, usually after a wash step. Each bead passes first through a red diode laser beam, in which measurements of side scatter and of the fluorescences (658 nm and >710 nm) of the color coding dyes are made, and then through a 532 nm green YAG laser beam, in which the fluorescence of the reporter reagent is measured. Side scatter signals are used to eliminate bead doublets and triplets from analysis; single beads are then classified by their color-coding, and distributions of reporter fluorescence associated with each bead type are analyzed to quantify the amount of each analyte of interest present in the sample.

Before producing the Model 100, Luminex made a series of beads that could be used for multiplex assays on a B-D FACScan; red- and orange-fluorescent dyes were used for color coding, and fluorescein or another dye with a similar spectrum was used as a reporter label. A PC-based data analysis system, attached to the FACScan, was used for calculating assay results. A number of publications describing multiplex analysis using Luminex beads have appeared in the literature<sup>23,10-5,3021</sup>.

Other companies, including **Bangs Laboratories** and **BD BioSciences**, have produced bead sets and assays using smaller numbers of beads, color coded by different intensities of a single fluorescent dye. There is a recent report of the use of the BD Biosciences kit for determining cytokines in tears<sup>3022</sup>, and, no, I don't mean that the cytokines were emotionally upset.

Other coding schemes are possible; **Quantum Dot Corporation** has made beads tagged with mixtures of quantum dots of differing emission wavelengths<sup>2648-9</sup>; **3D Molecular Sciences** has produced plastic particleless approximately 100  $\mu\text{m} \times 20 \mu\text{m} \times 15 \mu\text{m}$  with “bar coding” based on width variations along the length of the particle, detectable by pulse shape analysis of a scatter or extinction pulse<sup>3023</sup>. These beads could presumably be used in a relatively inexpensive single-laser instrument.

### Cells in Gel Microdroplets and on Microspheres

James Weaver and his colleagues at the Massachusetts Institute of Technology<sup>1837-43</sup> and, somewhat later, Eli Sahar and Raphael Nir and others at Tel Aviv University<sup>1844-8</sup> explored applications of the **gel microdroplet technique** originally described by Weaver et al<sup>1837</sup>, in which single or multiple bacteria or eukaryotic cells are observed visually or cytometrically after encapsulation in agarose gel beads from 10-100  $\mu\text{m}$  in diameter.

The method was originally envisioned as facilitating flow cytometric analyses of microorganisms, which, because of their small size, produce scatter signals which are difficult to detect in modern flow cytometers and which were impossi-

ble to detect in many older instruments. Since the nucleic acid content of microorganisms is approximately 1/1000 that of eukaryotic cells, fluorescence signals from microorganisms stained with propidium, DAPI, and other dyes which produce very strong signals from eukaryotic cells are also relatively weak; immunofluorescence signals would be correspondingly weaker. This made it infeasible to use fluorescence signals as trigger signals for flow cytometric analysis of microorganisms; however, the scatter signal from a 10  $\mu\text{m}$  gel microbead could provide a robust trigger signal, allowing a fluorescence measurement to determine whether an organism (s) was(were) contained in the bead.

This rationale for the use of gel microdroplet technique has largely disappeared due to increases in the sensitivity of commercial flow cytometers; it is possible to quantify bacterial growth by direct analysis of cultures from liquid media, without the additional step of encapsulating the organisms in microdroplets. However, the method is potentially useful for other applications. When single organisms are encapsulated in microdroplets and allowed to grow, the entire clone produced by successive divisions remains in a single droplet (Figure 10-12), facilitating selection of colonies<sup>1842,1845-8</sup>.

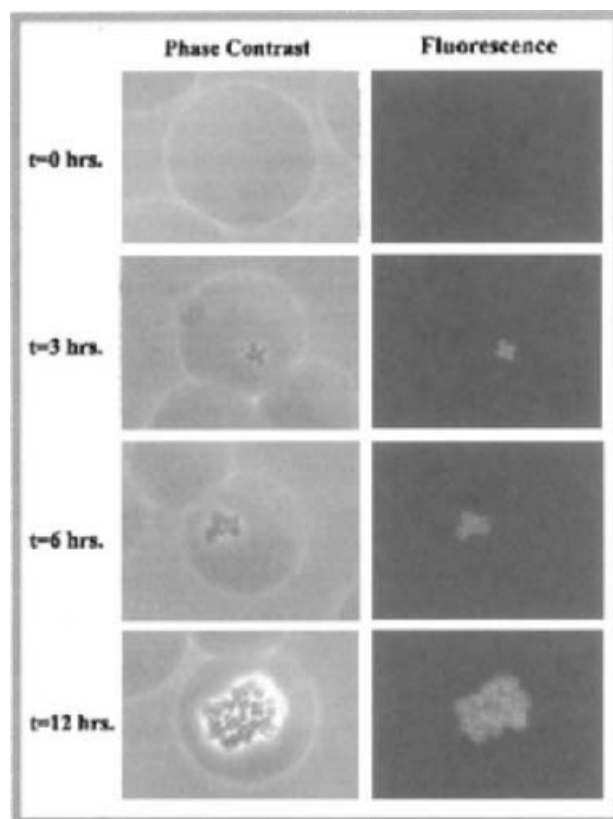

Figure 10-12. Growth of an encapsulated Gram-positive marine bacterium in gel microdroplets. Courtesy of Pat McGrath and Swee Kim Lin (One Cell Systems).

Such selection can be done on the basis of growth characteristics or on the basis of detection of metabolic products, which accumulate in the microdroplet<sup>1839</sup>. When applied to antibody-producing cells, the microdroplet technique represents a further diminution of scale over the microtiter plate<sup>1840</sup>.

The production of microdroplets is relatively straightforward; cells in medium are added to an agarose mixture, which is added dropwise to dimethylpolysiloxane oil, in which it forms an emulsion. A kit<sup>1843</sup> is available from **One Cell Systems** (Cambridge, MA); McFarland and Durack have provided recipes "for the frugal investigator"<sup>3024</sup>. Cells can readily be released from microdroplets, e.g., by adding agarase, for growth in culture or further processing.

Under normal circumstances, most of the microdroplets (about 90 percent) will be unoccupied by cells, and those that are occupied will initially contain only a single cell. In most cases, forward and side scatter signals are sufficient to discriminate between occupied and unoccupied droplets, as shown in Figure 10-13; the fluorescence of dyes such as propidium can be used to identify dead cells. Viable cells can be stained for DNA with Hoechst 33342, providing a fairly precise estimate of the numbers of cells in colonies, or stained for total nucleic acid with SYTO-9 (this fluorescent dye was used in the cells shown in Figure 10-12), which provides a usable, if less precise, assessment of growth.

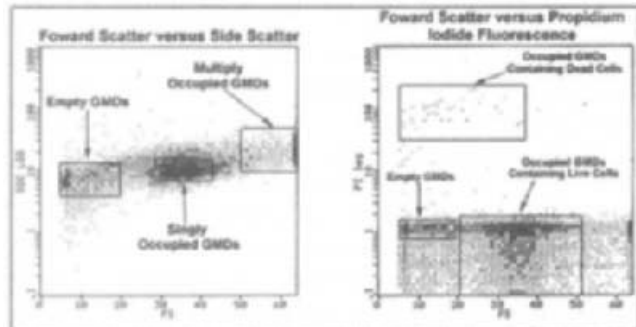

Figure 10-13. Identification of occupied and unoccupied gel microdroplets. Courtesy of Pat McGrath and Swee Kim Lin (One Cell Systems).

By incorporating appropriate antibodies in the gel, microdroplets can be made to capture one or more secreted products, which can then be detected using a second, fluorescently labeled, antibody<sup>1840,3025-6</sup>. However, the newer **cell-surface affinity matrix** technique<sup>2704-5</sup> may provide an equally effective means for detection of secreted products without the need for microdroplet generation or subsequent release of cells.

The use of gel microdroplets for such applications as antibiotic sensitivity testing, in which a dozen or more aliquots of sample subjected to different drug treatments must be analyzed, might be facilitated by multiplex color coding of the microdroplets; I am not aware that anyone has actually tried this.

## Hanging Ten Pseudopodia?

In order to preserve characteristics of these normally adherent cells during flow cytometric analysis, Bloch, Smith, and Ault<sup>1849</sup> attached human monocyte-macrophages to 14-20  $\mu\text{m}$  plastic microspheres; the cells retained phagocytic capacity, and could be maintained in long-term culture, stained for surface antigens, and examined and sorted while still in the adherent state. The technique should be applicable to other adherent cell types.

## 10.5 SINGLE CELL ANALYSIS: WHEN FLOW WON'T DO

From about the mid-1990's on, there has been an interesting interplay between high-sensitivity cytometry and high-sensitivity analytical chemistry. Richard Zare and his coworkers at Stanford<sup>3027-8</sup> exploited single cells as chemical detectors, using patch-clamp measurements of transmembrane electrical current and fluorescence measurements of intracellular calcium to quantify extremely small amounts of neurotransmitters and other ligands emerging from a capillary after electrophoresis.

Nancy Allbritton, who had been involved in that work, set up shop at the University of California at Irvine, and put the cells at both ends of the electrophoresis capillary; her group has used both conventional fluorescence detectors and detector cells to measure materials extracted directly from single cells into electrophoresis capillaries<sup>3029-3032</sup>. They emphasize determination of kinase activities in individual cells and in discrete regions of *Xenopus* oocytes.

Norm Dovichi et al<sup>3033-8</sup>, now at the University of Washington, are doing what they describe as **chemical cytometry**, i.e., "the use of high-sensitivity chemical analysis to study single cells"<sup>3033</sup>, and **metabolic cytometry**, "a form of chemical cytometry that monitors a cascade of biosynthetic and biodegradation products generated in a single cell"<sup>3035</sup>. The chemical analysis method they use is typically capillary electrophoresis. By using Hoechst 33342 fluorescence intensity, determined by image cytometry, as a criterion for cell selection, they have demonstrated variation of oligosaccharide metabolism during the cell cycle<sup>3033</sup>; they have also analyzed proteins from single cells<sup>3038</sup>. Their methodology has allowed them to detect as few as 50 molecules of a metabolic product. They have also made the point that, in addition to demonstrating cell-to-cell variation, analysis of single cells eliminates artifacts introduced in the preparation of extracts from cell populations for chemical analyses.

A special issue of *Current Opinion in Biotechnology* (Volume 14, Number 1, February, 2003) devoted to Analytical Biotechnology, and edited by Norm Dovichi and Dan Pintel<sup>3039</sup>, contains an article on kinase measurements by Sims and Allbritton<sup>3032</sup>, some informative papers on analysis of single mitochondria<sup>3040</sup> and single cell electroporation<sup>3041</sup>, and a review and update by Ibrahim and van den Engh on high speed sorting<sup>3042</sup>.

## 10.6 APPLICATIONS OF FLOW CYTOMETRY

We now get into the area(s) in which I can't even attempt to keep up with the literature. Coverage from here on may be arbitrary and capricious at times. However, in the course of preparing this edition, I appealed far and wide for people working in the field of flow cytometry to send me references, reprints, figures, data, URLs, etc., so don't blame me if you didn't send me anything and I missed something you did, however near it might have been.

I haven't excised the older references from this section, or, for that matter, from the rest of the book; choosing instead to put them into historical perspective as necessary.

### Cell Differentiation, *Ab Ovo* and *De Novo*

A broad range of applications of flow cytometry in studies of cellular differentiation was envisioned by Donna and Tom Jovin<sup>309</sup> in the early 1970's, at which time their voices and those of a very few others seemed to be crying in the wilderness. So it goes in the prophecy business. The use of flow cytometry to detect and quantify **variations in antigens, nucleic acids, enzymes, and functional characteristics during normal and abnormal differentiation** is now commonplace. This is an area in which multiparameter analysis can be particularly useful. If one wants to determine, for example, whether different gene products are being produced simultaneously or sequentially, single cell analysis can provide information that is unavailable using more traditional biochemical approaches.

A study by Swartzendruber, Travis, and Martin<sup>531</sup> of BrUdR-induced differentiation in mouse teratocarcinoma cells provided a good illustration of the range of parameters that could be analyzed in the late 1970's. These authors studied multiangle light scattering behavior, DNA content, and enzyme kinetics in BrUdR-induced and spontaneously differentiating cells.

Interest in the role of cytoplasmic  $[Ca^{2+}]$  and other functional parameters in the control of cell differentiation has also provided motivation for studies using flow cytometry, e.g., work by Levenson et al<sup>532</sup> on changes in mitochondrial membrane potential during the differentiation of Friend mouse erythroleukemia cells. Much of the earlier, and a fair amount of the later work in the area of blood cell differentiation has been done with leukemic cell lines such as HL-60 and K562, which, like Friend cells, undergo differentiation *in vitro* in response to a variety of chemical agents, including phorbol esters, DMSO, butyric acid, and retinoic acid. I'll cover more of blood cell development in the discussion of hematology and immunology.

As to development in general, it might be fair to say that, at least from a flow cytometric point of view, ontogeny has recapitulated hematology. We always knew that blood stem cells were in there somewhere; once enough monoclonal antibodies to leukocyte surface antigens had been raised, we managed to find the stem cells and clarify the developmental pathways. We now routinely harvest and transplant autolo-

gous and allogeneic blood stem cells, aided by cytometry at most steps along the way, and cytometry has also helped us define and mass produce some of the cytokines we use to extract an extra measure of performance from a hematopoietic system damaged by disease and/or drugs.

While we haven't come nearly as far in terms of taming embryonic stem cells, or stem cells that might help us regenerate damaged nerves or cardiac muscle, the model is now in place.

**Embryonic stem cells** have become a politically hot topic as well as a scientifically hot one. Flow cytometry has been used to analyze patterns of surface marker expression in stem cell differentiation<sup>3043</sup>, and, with sorting, to detect and select cells that have maintained their embryonic characteristics<sup>3044</sup> and/or cells potentially useful for transplantation by virtue of differentiation along a specific pathway<sup>3045</sup>. **Multi-potent adult progenitor cells (MAPC)** are of great scientific interest and may offer a less politically charged therapeutic alternative; their differentiation is studied using arrays to follow genotypic changes and flow cytometry to follow phenotypic ones<sup>3046</sup>.

### Differentiation in the Nervous System

I can't hope to cover the state of the art in every organ system, but I will call your attention of the work of Jeffery Barker, Dragan Maric et al at the National Institute of Neurologic Disorders and Stroke, National Institutes of Health, on nerve cell differentiation<sup>3047,533</sup>. They have used analyses of the cell cycle, of protein expression, and of calcium and membrane responses to neurotransmitters to define and fractionate populations of stem and differentiated cells, and to determine patterns of expression of different receptors and ion channels during differentiation. Following on work by Morrison et al<sup>3054</sup>, who sorted neural stem cells from embryonic peripheral nerves, and Rietze et al<sup>3055</sup>, who sorted stem cells from the adult central nervous system, both using positive selection strategies, the Barker group developed negative selection criteria, isolating stem cells on the basis of failure to stain with any of a combination of markers for differentiation and apoptosis<sup>3053</sup>.

### Whole Embryo Sorting

Working with Herzenberg and others, Krasnow<sup>1867</sup> used the lacZ reporter gene (pp. 408-9) to identify cells from portions of bearing defined mutant genes known to be differentially expressed in different segments or regions of the embryo. With dissociated whole early embryos as the starting material, neuronal precursor cells were sorted; they differentiated into neurons with high efficiency in culture. Incipient posterior compartment cells that expressed the *en* and *wg* genes were also purified from early embryos; Cumberledge and Krasnow<sup>1863</sup>, using such isolated cells, demonstrated that the *wg* protein provides a signal needed to maintain *en* expression. At the time at which these studies were done, and described as "whole embryo sorting," there were probably not a lot of people contemplating sorting whole

embryos, as opposed to a whole embryo's worth of isolated cells. Since then, Furlong et al, based in the same building as the Herzenberg lab, have developed and built an instrument that sorts whole *Drosophila* embryos<sup>325</sup>; you can build one from their plans (p. 266) or buy a similar device from **Union Biometrica** (p. 432).

## Somatic Cell Genetics and Cell Hybridization

### Reporter Genes Revisited

Much of the early work on the use of flow cytometry and sorting to isolate cells bearing transferred genes coding for specific human cell surface antigens from heterogeneous populations produced by cell hybridization and/or gene transfer was done in Ruddle's laboratory at Yale<sup>533</sup> and in Herzenberg's laboratory at Stanford<sup>534</sup>. In most cases, repeated sorting was needed to enrich cells bearing the desired antigens, which typically represent only a few hundredths of a percent of the cell population when the process is started. Le Bouteiller et al<sup>535</sup> described a method for quantitative analysis of expression of cloned HLA antigens in transfected cells.

I was somewhat surprised that repetitive sorting became a method of choice for isolation of small subpopulations of cells following gene transfer, especially since the procedure often began with the pooling of clones grown in isolation on solid or in semisolid media. It seemed to me that other assay methods, e.g., enzyme-linked immunoassay (ELISA), should have been sufficiently sensitive to identify the desired clones *in situ*, eliminating the pooling and sorting. This evidently reflected a more pronounced awareness of the shortcomings of flow cytometry than of the shortcomings of ELISA on my part.

The use of lacZ (p. 320)<sup>1642-4</sup> as a reporter gene detectable by fluorescence made it considerably easier to sort transfected cells, as the whole embryo sorting experiments discussed above indicate. And, in the previous edition of this book, it was noted that "the *Aequorea* green fluorescent protein<sup>1648</sup> (not yet used at the time) also looks promising for this purpose." The promise has been kept, and improved instrument sensitivity and sorting speed have made the job easier, although a few rounds of sorting may still be required.

### Isolating and Characterizing Hybrid Cells

Sorting can also eliminate the need for selective media for **separating hybrid cells or cybrids following a cell fusion** experiment. Schaap et al<sup>536</sup> used dual labeling techniques to identify and sort cell hybrids; Jongkind and Verkerk<sup>536</sup> combined cell sorting with ultramicrochemical analysis of single sorted cultured human fibroblasts to permit **determination of enzyme activity in individual sorted cells** for genetic analysis. Tertov et al<sup>532</sup> used **energy transfer between tracking dyes** with different spectral characteristics to identify and sort hybrid cells. Tracking dyes, particularly those that label membranes, e.g., "DiI," "DiO," and the

PKH dyes (pp. 371-4) still provide the easiest approach to detecting hybrids.

Trask et al<sup>1866</sup> used bivariate flow karyotyping (see next section) and FISH (pp. 361-2) to characterize hybrid cells bearing human chromosomes, while Bouvet et al<sup>567</sup> employed the former technique to identify pig chromosomes in pig-mouse hybrid cells. Some pig chromosomes could not be identified with certainty due to overlap with mouse chromosomes in the karyotypes; this could presumably be remedied by the use of fluorescent probes for the pig chromosomes, which should hybridize to regions containing oinkogenes. Sorry; my humor has peaks and troughs.

### Chromosome Analysis and Sorting and Flow Karyotyping

It was noted in the mid-1970's<sup>1106,3056</sup> that individual chromosomes stained with a single DNA fluorochrome could be measured by flow cytometry, producing a **univariate karyotype** (Figure 10-14).

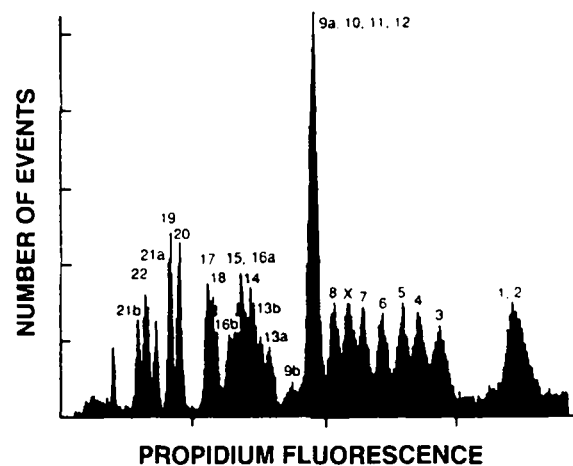

Figure 10-14. Univariate flow karyotype of human chromosomes stained with propidium iodide. From: Gray JW, Cram LS: Flow karyotyping and chromosome sorting. In: Melamed MR, Lindmo T, Mendelsohn ML (eds): *Flow Cytometry and Sorting* (2 Ed). New York, Wiley-Liss, 1990 (reference 1028), © John Wiley & Sons, Inc. Used by permission.

Although peaks representing most of the human chromosomes are discernible in the univariate karyotype of Figure 10-14, there is too much overlap between adjacent peaks for chromosomes to allow any given chromosome to be highly purified by sorting on the basis of propidium fluorescence alone. This reflects the fact that there are only small differences in DNA content between adjacent chromosomes.

The chromosomes shown in Figure 10-14 are stained with propidium, which is not highly selective for either A-T or G-C base pairs. By 1980, Langlois et al<sup>2778</sup> had established that combinations of DNA fluorochromes that exhibited **base preferences** for A-T (e.g., Hoechst 33258 and DAPI) or G-C (e.g., chromomycin A<sub>3</sub> and mithramycin) could be used to produce a **bivariate karyotype** (pp. 317-9; Figures

7-13 (p. 318) and 10-15), allowing discrimination of chromosomes that are similar in total DNA content but contain different proportions of A-T and G-C base pairs.

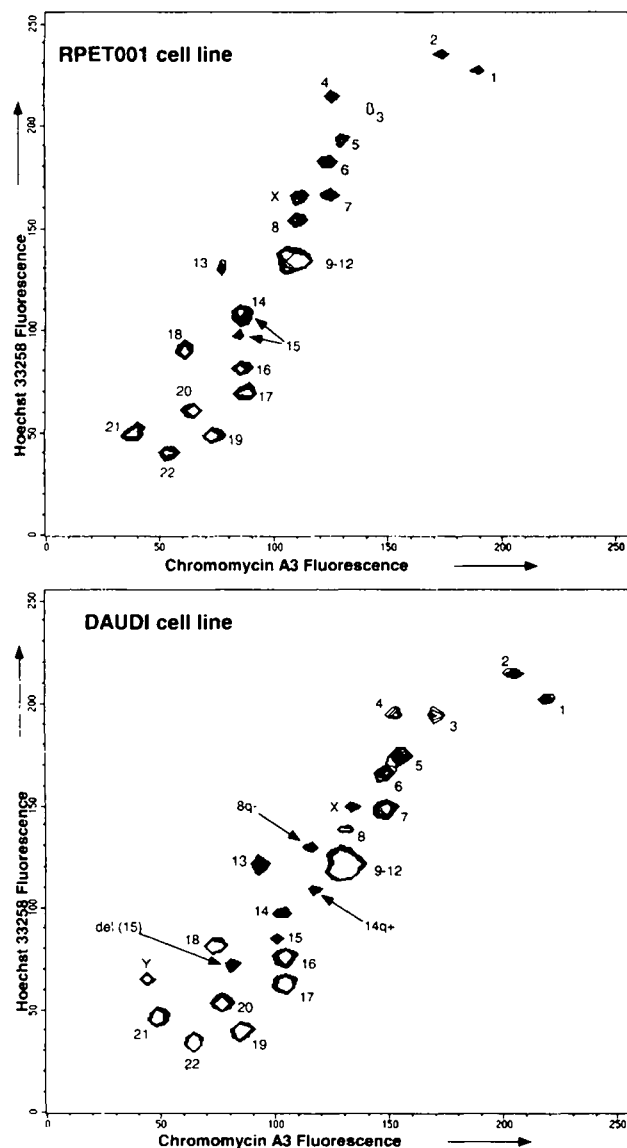

Figure 10-15. Bivariate karyotypes of RPET001 (top panel) and Daudi (bottom panel) human cell lines, based on Hoechst 33258 and chromomycin A<sub>3</sub> fluorescence. Courtesy of Simon Monard (Trudeau Institute).

A comparison of Figures 10-14 and 10-15 shows that the bivariate karyotype, unlike the univariate karyotype, places most of the human chromosomes in distinct clusters, making it relatively simple to purify individual chromosomes by sorting. **High-speed chromosome sorters**<sup>667,904</sup> with dual-beam illumination from high-power, water-cooled argon ion lasers (UV for Hoechst 3325, 457 nm for chromomycin A<sub>3</sub>) were developed and used at Livermore and Los Alamos to do this, facilitating the task of mapping the human genome and yielding chromosome-specific probes now used for fluores-

cence in situ hybridization (FISH)<sup>27,10</sup>. During the earlier stages of the genome project, when the first two editions of this book were written, it was common for experimenters to spend hours or even days sorting enough of a particular chromosome to build a genomic library<sup>537</sup>; amplification techniques have since made it possible to work with much less starting material, even as little as a single sorted chromosome<sup>3057-60</sup>.

Even before high-speed sorters became commercially available, Los Alamos also kept at least one dual-beam commercial instrument busy sorting chromosomes with good results. I was told by Scott Cram that reasonably good resolution of major groups of ethidium bromide-stained chromosomes in univariate karyotypes could be achieved using instruments with low-power argon laser sources, e.g., the Coulter EPICS Elite and B-D FACScan; any skepticism I harbored on this subject vanished when I saw karyotyping done as a lab exercise at one of the annual flow cytometry courses.

While it has been demonstrated that bivariate flow karyotyping of chromosomes stained with a Hoechst dye or DAPI (with an A-T base preference) and chromomycin A<sub>3</sub> or mithramycin (with a G-C base preference) can be done using air-cooled He-Cd lasers instead of much larger water-cooled ion lasers<sup>1133-5,1242</sup> as light sources, the He-Cd sources do not put out quite enough power to achieve photon saturation of the dyes, and are noisier than ion lasers, with the result that CVs are higher and separation of chromosomes in the measurement space is not as good. However, it seems likely that the UV and 457 nm ion lasers now used in bivariate chromosome sorters could be replaced by mode-locked 355 nm YAG lasers and 457 nm ND:YVO<sub>4</sub> lasers, both available at power levels on the order of those achievable with large ion lasers.

Asymmetric cyanine<sup>1133-4,1331</sup> dyes of the TOTO and TO-PRO series (see p. 315) have also been shown to produce bivariate flow karyotypes, although resolution is much poorer than that obtained with Hoechst 33258 and chromomycin A<sub>3</sub>. Buoyed by preliminary results, I spent several years exploring cyanines and a variety of other dyes in an ultimately unsuccessful search for combinations that could produce bivariate karyotypes using 488 and 633 nm laser sources. Unless someone else has better luck, bivariate karyotyping will continue to depend on the dyes we know and on instruments with UV and blue-violet excitation; with luck, the instruments will get smaller.

Reviews and descriptions of preparative and analytical techniques for flow karyotyping and results appeared in a number of earlier papers<sup>538-47,903, 1868-70</sup>; the 1989 book *Flow Cytogenetics*<sup>1050</sup>, edited by Joe Gray, remains an indispensable basic reference. Since the previous edition appeared, Lucretti and Doležel<sup>3061</sup> and Šimková et al.<sup>3062</sup> have described methods for analysis and sorting of plant chromosomes, Ferguson-Smith has reviewed the use of chromosome sorting and painting in phylogenetics and diagnosis<sup>3063</sup>, and Monard has discussed chromosome analysis and sorting<sup>3064</sup>.

Unless chromosome suspensions are well prepared, which is nontrivial (see reference 1050), the best instrument in the world won't provide flow karyotypes with good resolution. Kuriki, Sonta, and Murata<sup>1871</sup> consider the effects of isolation buffers in karyotyping hamster chromosomes, and Telenius et al<sup>1872</sup> point out that contamination by chromatids can degrade the resolution of bivariate karyotypes.

It was suggested that flow cytometry would eventually be useful for karyotyping for clinical purposes; Arkesteijn et al<sup>1873</sup> analyzed karyotypes in various lineages of blood cells in cases of acute myelocytic leukemia. Figure 10-15 illustrates differences in bivariate karyotypes between the RPET001 cell line, derived from nonmalignant cells, and the Daudi cell line, derived from a leukemia. The Daudi karyotype in the bottom panel of the figure shows abnormalities due to a translocation between chromosomes 8 and 14 (a frequent occurrence in leukemias) and a deletion on chromosome 15. However, while chromosome sorting continues to be of some interest to researchers studying genetic diseases involving translocations and other gross chromosomal abnormalities, flow karyotyping, which requires both expensive apparatus and relatively labor-intensive sample preparation techniques, does not now seem slated for extensive clinical use.

Rabinovitch, Martin and Hoehn<sup>548</sup> have considered one possible alternative, i.e., the detection of small degrees of aneuploidy in interphase cells by DNA content determination, as is done in determining effects of clastogenic agents (p. 453). This also requires a well-standardized, reproducible preparative method and an instrument with good precision and reproducibility. It is also abundantly clear that, where it can be accomplished, DNA sequence detection, e.g., using FISH, provides better and more specific genetic information than is available from karyotyping.

The overall strategy for flow karyotyping a previously uninvestigated species involves isolation and preparation of metaphase chromosomes, followed by generation of a univariate flow karyotype. If the univariate karyotype reveals a number of chromosomes with DNA contents too close to one another to permit good resolution of individual peaks, a bivariate karyotype is analyzed; however, unless there are substantial differences in base composition between chromosomes with similar DNA contents, bivariate karyotyping will not improve resolution<sup>3065</sup>. When neither univariate nor bivariate karyotyping succeeds in resolving most or all of the chromosomes well enough to permit purification by sorting, it is common to analyze mutants in which substantial chromosome translocations and/or chromosome polymorphisms are found<sup>3066-8</sup>; this typically makes it easier to sort at least parts of some otherwise unobtainable chromosomes. It has also been possible to introduce single chromosomes from other species into cell lines by somatic cell hybridization, facilitating their purification by sorting<sup>3069</sup>.

FISH<sup>3070</sup> and primed in situ labeling (PRINS)<sup>3071</sup> may be used to confirm identification of sorted chromosomes, usually based on identification of known repetitive sequences. Recently, Gygi et al<sup>3072</sup> reported the use of fluorescent se-

quence-specific **polyamide probes** (see Chapter 12) to distinguish human chromosome 9 from the other chromosomes with which it clusters on both univariate and bivariate histograms.

Rens et al<sup>2311</sup> described implementation of a slit-scan procedure for chromosome analysis and sorting which can be carried out on slightly modified commercial instruments. Stepanov et al<sup>3073</sup> described a flow cytometer in which mitotic cells are disrupted in the flow injector needle, releasing individual chromosomes and thus providing individual karyotypes on a cell-by-cell basis.

## Probing Details of Cellular Structures and Inter- and Intramolecular Interactions

### Dissection of Structures Using Antibodies, Ligands, and Genetic Methods

Since the late 1980's, flow cytometry has seen increasing use as a means of defining which regions of transmembrane and cell membrane associated proteins are actually exposed at the cell surface rather than embedded in the membrane. Studies of this type may make use of various combinations of monoclonal antibodies raised against different defined epitopes of isolated proteins, cells expressing mutant proteins, and ligands; flow cytometry provides quantitative answers as to which antibodies and/or lectins bind, and under what circumstances, and provides a powerful tool for structural analysis. This application is exemplified by work by Takahashi, Esserman, and Levy<sup>1513</sup>, who showed that the transferrin receptor is exposed differently in low- and high-grade lymphoma cells, and by investigations by Klebba et al<sup>1514-5</sup> on transmembrane proteins in Gram-negative bacteria.

### Intramolecular Interactions

A number of flow cytometric procedures for detecting inter- and intramolecular interactions are based on measurement of fluorescence resonance energy transfer (FRET)<sup>2347</sup> (pp. 283-4). Because the intensity of energy transfer is proportional to the inverse sixth power of the distance between the donor and acceptor fluorophores, slight changes in the distance between two suitably labeled interacting molecules result in large changes in energy transfer, providing a sensitive method for analyses of such phenomena as receptor-ligand interactions and changes in receptor subunit conformation. The first such studies were done using covalent labels on the molecules or submolecular units involved; more recently, it has become possible to clone suitable energy transfer pairs of fluorescent proteins into the structures of protein subunits between which interactions occur<sup>2377-8</sup>.

Michnick and coworkers<sup>3074-6</sup> have taken an alternate approach. They have engineered subunits of enzymes such as dihydrofolate reductase and  $\beta$ -lactamase, and can produce cells containing signaling proteins in which each of the two moieties involved in interaction contains a cloned inactive subunit of the reporter enzyme. When the inactive subunits become sufficiently close to one another as a result of

changes in the conformation of the signaling protein to which they are attached, they form an active binding site for the enzyme substrate. Active dihydrofolate reductase is detected by binding of fluorescently labeled methotrexate derivatives<sup>354,6</sup>; active  $\beta$ -lactamase is detected using the fluorogenic substrate CCF2<sup>2877</sup> (p. 409).

### Clinical Flow Cytometry: Turf and Surf

The first review of clinical applications of cytometry was published in 1981 by Laerum and Farsund<sup>386</sup>. The Engineering Foundation and the Society for Analytical Cytology co-sponsored conferences on Clinical Cytometry in April, 1982<sup>387</sup> and December, 1983. While the proceedings of the first of these meetings were not published, a symposium volume containing papers presented at the second did appear<sup>9,9</sup>.

Beginning in September, 1986, a series of annual meetings on Clinical Applications of Cytometry were organized by Dr. Mariano La Via of the Medical University of South Carolina and others and held in Charleston, South Carolina; this led to the founding of the Clinical Cytometry Society, and, subsequently, to the inclusion of a volume on clinical cytometry (originally subtitled *Communications in Clinical Cytometry*, now simply called *Clinical Cytometry*) in each year's issues of the journal *Cytometry*. Numerous sessions, symposia, and courses on clinical cytometry, flow and otherwise, have been held at and/or in conjunction with meetings of a number of organizations concerned with those areas of laboratory medicine in which flow cytometry has had the greatest impact, i.e., hematology, immunology, and oncology (see Chapter 2 for details).

The earlier reviews<sup>906,980,2</sup> of clinical cytometry have been replaced by a number of books (also see Chapter 2). The most recent book dedicated to clinical flow cytometry is the Third Edition of *Flow Cytometry in Clinical Diagnosis*<sup>3393</sup>, edited by Keren, McCoy, and Carey, published in 2001; I would also recommend a 2001 volume in *Clinics in Laboratory Medicine* on "New Applications of Flow Cytometry"<sup>2398</sup>, edited by McCoy and Keren. Also of general interest is an online journal, *Case Studies in Clinical Flow Cytometry*, edited by Michael Borowitz and endorsed by both the Clinical Cytometry Society and ISAC. The journal is accessible at <<http://www.flowcases.org>>.

Earlier editions of this book made attempts at complete coverage of existing and projected clinical applications of flow cytometry according to a framework that Brian Mayall<sup>983</sup> and I<sup>984</sup> independently followed in surveying the field at the 1983 Engineering Foundation-SAC conference. In the previous edition and this one, I have made and make no pretense of trying to cover the entire field.

Clinical cytometry itself has changed over the years. In the 1970's, most clinical cytometry was done by simple hematology counters, on the one hand, and by image analyzing automated differential counters, on the other. The differential counters scanned Wright's-stained smears, and could not identify different lymphocyte types. Clinical cytometry to-

day still involves flow cytometric hematology analyzers, which now perform differential counts as well as red and white cell, platelet, and reticulocyte counts, often without benefit of fluorescence measurements. Fluorescence flow cytometers are used for a wide range of clinical tests, predominantly involving immunophenotyping and DNA content analysis, none of which is done anywhere near as often as are differential leukocyte counts or Papanicolaou smears.

A new breed of image analysis systems have come into clinical cytometry to facilitate and perform Pap smear screening for cervical and other gynecologic cancers, but, by and large, the people who deal with these systems publish in *Acta Cytologica* (<http://www.acta-cytol.com>) and *Analytical and Quantitative Cytology and Histology* (<http://www.aqch.com>), both of which are official journals of The International Academy of Cytology and The American Society of Cytopathology. The blood cell counter people tend to publish in *Laboratory Hematology* (<http://labhem.cjp.com/>), the official journal of the International Society for Laboratory Hematology, and the people who do clinical fluorescence flow cytometry are more likely to publish in *Cytometry* and *Clinical Cytometry*, and to go to meetings of the Clinical Cytometry Society and ISAC.

The turf issues in journals and societies mirror turf issues in hospitals and clinics. If the next successful clinical product incorporating a flow cytometer is built to do microbiology, or Pap smears, it is unlikely that the immunologists and/or pathologists who use their fluorescence flow cytometer to do immunophenotyping and DNA analysis will ever have much to do with it, and it is no more likely that the microbiologists or the cytopathologists would funnel a significant portion of their laboratory work load to the fluorescence flow cytometer in the clinical immunology lab, even if that instrument could do antimicrobial susceptibility tests or cervical cancer screening.

It was nicer when all of us went to the same meetings, but at least I (and you) can try to keep with lab hematology and cytopathology online. Hence my section title.

From this point on, I will deal with selected clinical applications of cytometry in the context of broader discussions of application areas. Phil McCoy has provided the bottom line for this section with a discussion of Medicaid and Medicare reimbursement for flow cytometry<sup>3077</sup>: you may be able to collect for doing reticulocyte counts, T cell counts, absolute CD4 and/or CD8 counts and ratios, single antigen [B27] HLA typing, immunophenotyping, and DNA content/cell cycle analysis.

## Hematology

### Clinical Application: Blood Cell Counting and Sizing

Before photoelectric<sup>48</sup> and electronic<sup>49</sup> cell counters were developed in the 1950's, the **counting and classification of blood cells** had to be done by human observers (pp. 77-9). Coulter's apparatus was introduced into laboratories in the

1960's and shown to be superior for **red cell counting**<sup>50</sup> and **sizing**<sup>51</sup>; the use of selective lysing agents to remove red cells made it feasible to do **white cell counting** with the same instruments. Acceptance came rapidly; the instrumentation was rapid, laborsaving, and produced more accurate and precise results than could be obtained by even the most dedicated, highly trained personnel.

It was slightly harder to make electronic counters count **platelets** because these cells were smaller in size, and thus produced smaller signals, which were harder to discriminate from noise. Nonetheless, electronic counting was perceived as the method of choice for platelet counting some time before it could actually be used effectively for the task. Modern hematology analyzers now count and size all formed elements in blood.

Fundamental issues and principles of cell counting were introduced on pp. 18-21. Commercial hematology instruments were covered briefly on pp. 433-4. Automated blood counts, and automated differential counts as well, are discussed in some detail in books by Bessman<sup>985</sup> and Groner and Simson<sup>2915</sup>. NCCLS (see p. 361) has issued an Approved Standard<sup>3078</sup> for quality control of hematology analyzers with recommended goals for accuracy and precision in measurements of hemoglobin concentration, erythrocyte, leukocyte, and platelet counts, and mean corpuscular volume.

### Red Blood Cells (Erythrocytes)

#### Clinical Application: Reticulocyte Counts

Counting the relatively small fraction of RNA-containing immature cells, or reticulocytes (see pp. 78-9, 99, 312-4, and 326), which normally comprise about 1 percent of circulating red blood cells, gets into the realm of rare event analysis when red cell production is impaired, and the fraction of reticulocytes in the total red cell population decreases. The job gets easier when red cell turnover is increased, e.g., following bleeding or in hemolytic anemias, and the reticulocyte count (usually expressed as reticulocytes/1000 RBC) increases.

The biology of red cell maturation dictates that the distribution of RNA content in cells should be continuous; the distinction between reticulocytes and mature erythrocytes in visual counting is made only when enough RNA is present to form a visible precipitate after staining with basic dyes. Flow cytometric approaches to reticulocyte counting should ideally be based on the determination of the RNA content distributions in red cell populations, because shifts in the distribution to lower or higher mean fluorescence values provide the same clues to red cell kinetics as are obtained from decreases or increases in the reticulocyte count. However, what often happens in practice is that cells are determined to be "positive" or "negative" for RNA.

The reticulocyte count is normally in the neighborhood of 1%, or 10 reticulocytes per 1,000 red cells; thus, visual reticulocyte counts, generally based on counts of 1,000 red cells, are inherently imprecise due to Poisson sampling er-

ror<sup>762,3</sup>; if  $n$  reticulocytes are actually observed, the standard deviation is  $n^{1/2}$ . If, on examination of 1,000 red cells, 16 reticulocytes are seen, the standard deviation is 4 cells, and the CV is 4/16, or 25%. Taking the observed value plus 2 standard deviations as the **95% confidence limits**, i.e., the range within which there is 95% probability that the true value will be found, the true reticulocyte count is likely to lie between 8/1,000 and 24/1,000 red cells.

The only way in which to improve the precision of reticulocyte counts is to count more cells. If a flow cytometer is used to count 100,000 red cells, and 1,600 reticulocytes are counted, giving the same 16/1,000 count discussed above, the standard deviation is 40, the CV is a more acceptable 2.5%, and the 95% confidence limits are now 15.2/1,000 and 16.8/1,000 red cells, narrowing the range considerably. The hardest part of validating flow cytometric methods for reticulocyte counting has been evaluating agreement of the new techniques with visual counting, because visual counts are so abysmally imprecise.

Although some hematology counters identify reticulocytes by measuring the absorption of a cell-associated dye such as oxazine 750 or the fluorescence of acridine orange, the more recent trend has been toward using dyes which increase fluorescence by factors ranging from several dozenfold to several thousandfold on binding to RNA, including asymmetric cyanines such as thiazole orange and related compounds such as thioflavin T and auramine O.

The fact that all these dyes are positively charged and lipophilic raises some questions as to the mechanism of reticulocyte staining. The membrane potentials of reticulocytes appear to be higher<sup>290,91</sup> than those of mature red cells; this should cause vitally stained reticulocytes to take up basic dyes more avidly than would mature cells. Thus, the less mature cells should contain more dye as well as more RNA, and the staining difference between mature and immature cells would be enhanced. The experiments necessary to determine what contribution, if any, cell membrane potential differences make to reticulocyte staining (i.e., comparisons of fluorescence levels between unfixed and fixed or gramicidin-treated cells) have not been reported to date.

Corash et al<sup>1783</sup> compared thioflavin T, ethidium bromide, and thiazole orange as reticulocyte stains, and found the latter two preferable because they required less precise control of dye incubation time. Subsequent studies by Carter et al<sup>1784</sup>, Van Hove et al<sup>1785</sup>, Hansson et al<sup>1786</sup>, and Schimenti et al<sup>1787</sup>, among others, have established the validity and utility of flow cytometric reticulocyte counts done with thiazole orange; they are, as might be expected, more sensitive than manual counts<sup>1786,7</sup>, in that they can detect cells with lower RNA levels. Thiazole orange reticulocyte counts can also be done on canine<sup>1788-9</sup> and feline<sup>1790</sup> blood. Van Petegem et al<sup>1791</sup> compared three benchtop flow cytometers, the B-D FACScan, Coulter EPICS Profile, and Ortho Cyturon Absolute, for reticulocyte enumeration using thiazole orange, and found the instruments gave equivalent results from counts of 30,000 cells. Guasch et al<sup>1793</sup> confirmed

the report of Van Bockstaele and Peetermans<sup>1792</sup> that the diethyl analogue of thiazole orange, 1,3'-Diethyl-4,2'-quinolythiacyanine iodide, yielded equivalent results.

Since thiazole orange stains DNA as well as RNA, red cells containing DNA due to the presence of intraerythrocytic parasites<sup>771,1788</sup>, Howell-Jolly bodies<sup>1785,1795</sup>, nuclei, or micronuclei become fluorescent when stained, and may be counted as reticulocytes; falsely high reticulocyte counts may also occur in the presence of red cell autofluorescence, giant platelets and high leukocyte or platelet counts<sup>1785,1796</sup>.

Dedicated flow cytometric reticulocyte counters, the R-1000 and R-3000, which measure RNA using argon ion laser excitation of auramine O fluorescence, have been developed by **Sysmex-TOA Medical Electronics** (Kobe, Japan)<sup>1797</sup>, and validated in several studies<sup>1798-1800</sup>; Bowen et al<sup>1801</sup> found substantially equivalent performance in a comparison of reticulocyte counting using thiazole orange on a B-D FACS and auramine O on a Sysmex R-1000. More recent studies<sup>3079,80</sup> confirm that automated reticulocyte counting is far more precise than manual counting and that a variety of commercial instruments are efficacious for the purpose. Riley et al<sup>3081</sup> have recently published an extensive review of reticulocyte counting methodology.

The obvious inadequacies of manual reticulocyte counts in terms of the number of cells counted and the difficulty of detecting cells with small amounts of RNA makes the manual count something less than a gold standard for comparison, creating a problem in validating flow cytometric counts. Oosterhuis et al<sup>1794</sup> have used a multivariate statistical model to compare manual and flow cytometric counts based on correlations of the results of each with hemoglobin concentration, mean cell volume, and erythrocyte density width, and found flow counts superior; their modeling method is generally applicable to tests in which reliable standard methods do not exist. NCCLS issued an Approved Guideline<sup>3082</sup> for reticulocyte counting in 1997, covering both flow cytometric and classical methods; Bruce Davis, who is working on a new guideline, tells me that a flow cytometric method based on thiazole orange will become the new gold standard.

There's just one little thing bothering me. I have done some work on reticulocyte counting over the years, aimed at finding red-excited dyes that would allow the use of inexpensive diode lasers instead of argon lasers in flow cytometric retic counters. As it happens, one of the newer counters from Sysmex does appear to use a red-excited dye. Now, the dyes used to stain retics are RNA dyes, and, if you stained blood with both a 488 nm-excited dye and a red-excited dye, and analyzed the cells in a dual-beam cytometer with 488 nm and red lasers, you would expect to see retics stained with both dyes. When I have tried this trick with thiazole orange and with a variety of putative red-excited retic stains, I find that there is some discordant staining; there are cells stained with both dyes, but there always seem to be cells stained with one dye and not the other. Maybe somebody out there would like to try the experiment using thiazole

orange and a manufacturer's approved red-excited retic reagent. It's another one of those things that I haven't gotten around to while I've been writing this.

### The Reticulocyte Maturity Index (RMI)

Since reticulocytes contain as much RNA as they ever will at the time at which they enter the circulation, and lose it over a period of a few days, the less mature reticulocytes will, on the average, contain more RNA than the more mature ones, and will therefore have higher fluorescence intensities when stained with dyes such as thiazole orange and auramine O.

Davis and Bigelow<sup>1802-4</sup> used either the mean fluorescence channel of the fluorescent cells or the fraction of highly fluorescent cells among the total number of reticulocytes as a **reticulocyte maturity index (RMI)**; the latter method was found to result in lower interlaboratory variability in a multicenter study<sup>1805</sup>, which also demonstrated lower variability among labs using the Sysmex R-1000 than was found using the thiazole orange method. This is to be expected, since the R-1000 methodology is more standardized. The RMI, independent of reticulocyte count, has been found to be predictive of successful engraftment following marrow transplantation<sup>1806-7</sup> and of marrow recovery after intensive chemotherapy<sup>1808</sup>, and a useful indicator of erythropoietic activity in anemia<sup>3083</sup>.

Bayer Diagnostics' hematology analyzers, which count retics based on absorption of oxazine 750<sup>737</sup>, calculate a reticulocyte maturity index from the fraction of cells with high absorption values. Other indicators of reticulocyte heterogeneity have been investigated. A monoclonal antibody which binds to relatively immature cells has been identified by Mechetner, Sedmak, and Barth<sup>1809</sup>, while Bain and Cavill<sup>1816</sup>, making use of the ability of a Technicon (now Bayer) hematology counter to measure both size and hemoglobin content of individual erythrocytes<sup>684,1811</sup>, showed that while reticulocytes are often hypochromic macrocytes, the percentage of hypochromic macrocytes does not accurately predict the percentage of reticulocytes.

### Erythrocyte Flow Cytometry: Other Clinical Uses

The detection of antibodies to cells is the bread and butter of **immunohematology**<sup>1005</sup>; a principal area of application is in **transfusion medicine**. Garratty and Arndt have discussed applications of flow cytometry in this field<sup>3085-6</sup>. Flow cytometric methods have been used<sup>1006</sup> to examine effects of regular blood component donation on donors, and for detection and quantification of specific cell-bound antibodies to platelets<sup>1007,1939</sup> and other cell types in **autoimmune cytopenias**. Changes in red cells<sup>1963</sup> during storage can also be monitored.

Davis<sup>3084</sup> has recently reviewed the use of flow cytometry in detecting **fetomaternal hemorrhage** by performing the equivalent of a **Kleihauer-Betke test**, and in detecting cells containing **hemoglobin F** and **intracellular parasites**.

## White Blood Cells (Leukocytes)

### Clinical Application: Differential Leukocyte Counting

While instrument developers anticipated that **flow cytometric differential white blood cell counters** would find the same rapid acceptance as had the earlier slide scanning systems, this was not to be. Differential counting, for better or worse, was intimately tied to the stained slide, and results obtained using fluorescent stains such as acridine orange<sup>61,588,9</sup> were discounted, even when confirmed by cell sorting<sup>590</sup>. **Technicon** (now **Bayer**)'s Hemalog instrument<sup>84,5</sup>, based on **enzyme cytochemical stains** which were widely known in hematology, was not well accepted when it was introduced to the market in the early 1970's, although its performance was demonstrably superior to that of any competing image analyzing differential counter.

In the mid-1980's, there was a resurgence of interest and commercial activity in flow cytometric differential counting. Manufacturers of electronic (e.g., Coulter) and photometric (Ortho) instruments designed for blood cell counting in clinical laboratories began to offer **3-part (lymphocyte/monocyte/granulocyte) differential counts** based on differences in electronic cell volume<sup>69</sup> or in orthogonal light scattering<sup>92,3,157,175,6</sup>, while other companies, recognizing the great success of Technicon's instrument, began to investigate the possibility of building inexpensive flow cytometric differential counters using new stains which could discriminate eosinophils and basophils from neutrophils, yielding a traditional **5-part differential count**.

It is apparent to most observers that there was a change in attitude toward flow cytometry on the part of clinical pathologists and laboratory hematologists in the mid-1980's; these clinicians were much more likely to accept a flow cytometric differential counter than they had been in the mid-1970's, not because the technology of differential counting had improved dramatically, but because the highly visible applications of flow cytometry in research in hematology and immunology made the technology not only respectable, but desirable. Future developments in this area will depend not on science, but on the economics of health care. As long as it is decided that 5-part differential counts are still worth doing in volume, even in modern cost-constrained clinical laboratories, there will be new instruments. There are a lot of ways to do differential counts by flow cytometry<sup>93</sup>, and the least complicated and least expensive will probably survive the natural selection process.

One of the more interesting approaches to the problem, implemented commercially by **Sequoia-Turner** (later **Unipath** and now **Abbott**)<sup>986</sup> in the Cell-Dyn 3000<sup>1921</sup>, 3500, and 4000 instruments, is based on the observation by de-Grooth et al<sup>710</sup> that **polarized and depolarized orthogonal light scattering signals can discriminate eosinophils from neutrophils** in unstained blood (pp. 278-9). Two-parameter

displays of a normal leukocyte population, obtained using one of these analyzers, are shown in Figure 10-16; the instrument measures scatter at smaller angles as well as orthogonal scatter.

**Coulter's VCS (Volume/Conductivity/Scattering)** technology uses measurements of DC and RF impedance and light scattering to perform a five-part differential count; it is implemented in the VCS<sup>1922,3</sup>, STKS<sup>1924</sup>, and MAXM hematology analyzers. Earlier instruments derived a differential count from the leukocyte volume distribution.

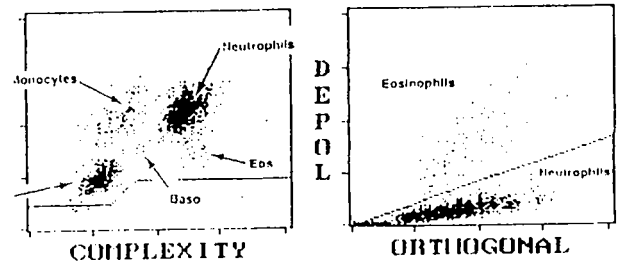

Figure 10-16. Clusters of peripheral blood leukocyte types in two-dimensional displays from an Abbott Cell-Dyn 3000 hematology analyzer. The figure was provided by Judy Andrews and Pamela Kidd (U. of Washington).

**Bayer's Advia** line, successors to the Technicon Hemalog and H-series instruments, retains the peroxidase staining used in the original Hemalog D, but have abandoned the Alcian blue basophil stain in favor of differential lysis, and identify monocytes based on their light scattering and low peroxidase content.

**NCCLS** (then the National Committee for Clinical Laboratory Studies) issued an Approved Standard on leukocyte differential counting in 1992<sup>3087</sup>. Since then, a number of comparisons of hematology analyzers have appeared in the literature<sup>1926-31</sup>. Bentley, Johnson, and Bishop<sup>1931</sup> did a comparative evaluation of the Unipath (now Abbott) Cell-Dyn 3000, Coulter STKS, Sysmex NE-8000, and Miles (Technicon) H-2, using the NCCLS protocol; they could not establish that any single instrument was clearly superior to the others. Buttarello et al<sup>1930</sup> reported similar results in a comparison of the same four instrument types.

Clinical hematology analyzers are designed to flag apparently abnormal bloods, because their capacities for detection of blasts, nucleated red cells, and immature granulocytes are limited. In general hospital and outpatient clinic settings, no more than 25% of samples are typically flagged, and thus require examination of a smear by a technologist or hematologist; in tertiary care institutions, over 60% of samples may be flagged. Nonetheless, automated differential counting still reduces technologists' and hematopathologists' workloads. If a more sophisticated apparatus that would flag fewer samples could be made cost-effective, there would probably be a substantial market for it.

The measurement parameters and methods and computer algorithms used in automated differential counters differ from instrument to instrument. Thus, while all instruments yield similar results, a careful comparison, such as the 1995 study of absolute lymphocyte counts published by Groner and Simson<sup>3088</sup>, will reveal the biases of individual analyzers. Biases in lymphocyte counts may become problematic when leukocyte and lymphocyte counts from a hematology analyzer are combined with data from a fluorescence flow cytometer to obtain a “two-platform” absolute count of CD4+ cells.

The development of automated differential counters has been hampered to a considerable extent by the lack of a true “gold standard.” Early in the game, it was thought that the results obtained by flow cytometric methods should agree with those obtained from visual analysis of Wright’s or Giemsa-stained smears by a well-trained hematology technician, hematologist, or hematopathologist. It soon became apparent that most flow cytometric counters yielded higher monocyte and lower lymphocyte counts than were reported from smears, even when the methodologies used in the flow systems were quite different.

For example, the Block prototype, which identified monocytes primarily by forward and right angle light scattering, the Technicon Hemalog D, which identified monocytes by the presence of intracellular esterase, and the Ortho Cytofluorograf, using acridine orange staining, produced concordant results that did not agree with manual counts; results based on scatter and acridine orange staining were confirmed by sorting at Los Alamos<sup>91</sup>. Evidence that the flow systems were right, and the human observers (and slide-scanning differential counters) wrong, was provided by a 1974 study by Zucker-Franklin<sup>3089</sup>, who examined peroxidase content, adherence to glass, and phagocytic capacity of mononuclear cells in human blood, and concluded that “the percentage of monocytes in normal blood is at least twice as high as is commonly recognized on routine smears.” It is evidently not possible to tell small monocytes from lymphocytes on a Wright’s-stained blood smear; this alone should disqualify it as a standard.

The cytochemistry and immunology of leukocytes are now considerably better understood than they were when most differential counters were developed, and it should be possible to identify the normal leukocytes (and any nucleated red cells) present in a peripheral blood specimen unambiguously using a combination of cytochemical stains, fluorescent antibodies, and light scattering characteristics.

Hübl et al<sup>3090</sup> proposed a reference method for the five-part differential count using a fluorescein-labeled anti-CD45 antibody, a PE-Cy5-labeled anti-CD14 antibody, and a cocktail of phycoerythrin-labeled anti-CD2, anti-CD16, and anti-HLA-DR antibodies; they reported good concordance with results of 500-cell manual differential counts, even for basophils, but sample preparation steps (lysis and washing) appeared to have some influence on counts.

To get a true “gold standard” count, it would be advisable to work with unfixed, unlysed whole blood samples and “no-wash” staining, using a vital nuclear stain to identify nucleated cells for triggering, to produce a differential count unbiased by any selective cell loss that might occur during lysis, fixation and/or washing. This seems entirely feasible.

Since all of the early development and most of the maturation of blood cells occur in the marrow, it is rare to have definitive diagnoses of hematologic diseases made on the basis of differential counts; what is usually required is an examination of a marrow aspirate or biopsy. This concept was difficult to get across to a lot of the engineering types involved in the development of the first generation of automated differential counters, who seemed to think peripheral blood differentials were the equivalent of a Pap smear for leukemia, and who also labored under the misconception that there were discrete categories of immature or “abnormal” cells which could be definitively identified by experienced hematologists. For at least some types of marrow examination, the flow cytometer can help the hematologist considerably more than the microscope can, and the hematologist may be able to drop out of the loop within a few years, or stay in it only to insure reimbursement.

### CD Characters: Leukocyte Differentiation Antigens

International Workshops on Human Leukocyte Differentiation Antigens must be held to periodically keep track of an increasing number of defined human leukocyte cell surface antigens<sup>905,1122-7</sup>. The **CD (Cluster of Differentiation)** nomenclature now standard for the common leukocyte antigens runs to CD247; the results of the 7th workshop, held in Harrogate in 2000, are available in book form<sup>3091</sup> and also in an extensive online database via *Protein Reviews on the Web*<sup>2431</sup>. An online index of CD antigens is at <<http://www.ncbi.nlm.nih.gov/prow/guide/45277084.htm>>. The 8th International Workshop, chaired by Heddy Zola, will be held in Adelaide in December, 2004; information is available at <<http://www.hlda8.org>>.

For a more portable work on CD antigens, see *The Leukocyte Antigen FactsBook*<sup>1874</sup>, edited by Barclay et al, now in its second (1997) edition<sup>3092</sup>. Academic Press’s “*FactsBook*” series includes a few other titles relevant to leukocyte immunology as well. *The Adhesion Molecule FactsBook*<sup>1875</sup>, with a 2000 second edition<sup>3093</sup>, describes the chemical characteristics and cellular specificities of **adhesion molecules**. *The T Cell Receptor FactsBook*<sup>3094</sup>, *The HLA FactsBook*<sup>3095</sup>, and *The Cytokine FactsBook and WebFacts*<sup>3096</sup> are also handy references.

### Granulocytes: Basophils

Basophils were originally so named by Paul Ehrlich on the basis of their propensity to accumulate cationic dyes in these granules at concentrations high enough to cause metachromasia, or shifts in the spectrum of dye. They are the rarest of the five major classes of peripheral blood leukocytes, usually comprising between 0.1% and 1.0% of cells in dif-

ferential leukocyte counts, or fewer than 50 cells/ $\mu\text{L}$  blood. They can be identified on smears stained with Giemsa's, Wright's, and similar eosin-azure blood stains by the metachromatic absorption of azure dyes bound to glycosaminoglycans and other components of their cytoplasmic granules. Basophils can also be identified in suspension by their metachromatic staining with dyes such as Alcian blue, Astra blue and toluidine blue.

### Basic Orange 21: The Best Basophil Stain Yet

Several manufacturers have investigated staining with a metachromatic dye described by Lawrence Kass, **Basic orange 21**<sup>987,3097</sup>, which can be used either as an absorption stain or as a fluorescent stain. Dr. Kass, who is on the faculty at Case Western Reserve University, inherited a large collection of textile dyes from his father, and, in the tradition of Paul Ehrlich, proceeded to determine whether he could see anything interesting using the dyes. Perhaps unfortunately for those of us in the cytometry game, he is a very good morphologic hematologist, which means that he can usually see distinctions too subtle for low-resolution instruments like flow cytometers to pick up.

Basic orange 21, unlike most metachromatic dyes, has a metachromatic absorption peak at a longer wavelength than its orthochromatic absorption peak (560 versus 483 nm). The dye is rapidly absorbed by living cells, and is apparently nontoxic in the short term. It stains neutrophil granules orange, eosinophil granules a darker orange-brown, and basophils a striking purplish red; the metachromatic spectral shift can be demonstrated in solution if concentrated heparin sulfate is added to the dye. Basic orange 21 is the best stain I have ever come across for **visual counting of basophils** (or, for that matter, mast cells) by transmitted light microscopy. It is completely trivial to count basophils in unlysed whole blood in a hemocytometer using the dye.

Basic orange 21 also yields excellent basophil counts in a flow system in which green-excited red fluorescence can be measured; it works quite well with low-power green He-Ne laser excitation at 543 nm (L. R. Adams, H. Shapiro, and L. Kass, unpublished), and Crippen, Nilsson, and Matsson<sup>2072,3</sup> showed that basophils and mast cells could be distinguished from other cells using 515 nm excitation from an argon laser. If all you have is 488 nm, you're out of luck; this is much better at exciting the orthochromatic fluorescence of the dye than the metachromatic fluorescence.

### Allergy Tests Using Basophil Degranulation

Basophils have receptors for IgE on their surfaces. Allergic individuals make IgE antibodies against substances to which they are allergic; these antibodies bind to the IgE receptors on basophil surfaces. Any allergen entering the circulation can cross-link IgE molecules bound to different receptors, initiating a signaling cascade that results in basophil degranulation, with the release of heparin, histamine, and a bunch of other stuff which, *in vivo*, leads to swelling, sneez-

ing, etc., and which, *in vitro*, can be detected by chemical analysis and used as the basis of tests for allergens<sup>1932,3</sup>.

Under most circumstances, the histamine release initiated by crosslinking of basophil cell surface IgE receptors is accompanied by loss of metachromatic staining. This forms the basis for the **basophil degranulation test (BDT)**<sup>3098,191</sup>, in which reactivity with allergen is assessed by counting the number of basophils (i.e., cells with metachromatic granules) in an untreated control aliquot of a specimen and in aliquots exposed to putative allergens. Degranulation can also be initiated by anti-IgE antibody, which also cross-links receptors carrying bound IgE.

Milson et al<sup>1934</sup> and Nilsson<sup>1935</sup> demonstrated that the older Technicon hematology instruments, such as the H6000, which had a separate channel for identifying basophils by Alcian blue staining of their granules, could be used to do basophil degranulation tests for allergy on whole blood. Since the later Technicon H-series instruments and their Bayer successors detect basophils differently, they cannot be used for the same purpose.

Unless basophils are concentrated from peripheral blood by density gradient sedimentation or centrifugation, the number of cells present in each aliquot examined in a BDT is likely to be small enough to make results imprecise due to sampling error. This figured prominently in the so-called "Benveniste Affair" of 1988, in which results of BDT's were erroneously interpreted by Jacques Benveniste's group as demonstrating degranulation of basophils by solutions from which anti-IgE had presumably been totally removed by serial dilution, evidently lending some credence to a basic tenet of homeopathy and to the theory that water can "remember" what has been dissolved in it. Their paper was accepted and published in *Nature*<sup>3102</sup>, with the condition that the Editor of *Nature* (John Maddox) be allowed to visit the Benveniste lab with colleagues of his choosing, scrutinize details of the original experiment, and observe a blinded attempt at repetition with rigorous controls. Maddox chose magician-debunker James ("The Amazing") Randi and NIH whistleblower/gadfly Walter Stewart to accompany him.

The BDT's in the Benveniste experiments were done by visual observation, and both sampling error and observer bias appear to have led the group to draw incorrect conclusions from the initial experiment. The experiment done with Maddox et al on hand found no apparent effect of high dilutions of anti-IgE, leading him and his colleagues to describe the original report as the result of a delusion<sup>3103,4</sup>.

During the 1990's, a number of groups investigated flow cytometric assays as possible replacements for the BDT<sup>3101</sup>; in 1994, Sainte-Laudy et al reported that CD63 on basophil surfaces was upregulated after activation, and that the results of flow cytometric assays based on this characteristic correlated well (and substantially better than do results of assays measuring loss of metachromasia) with results of histamine release assays. The assay is commonly done using fluorescent anti-IgE antibodies to identify the basophils and anti-CD63

to detect activation; a kit (BASOTEST) is available from ORPEGEN Pharma.

In 1999, Belon et al<sup>3105</sup> published results of a multicenter study, based on BDTs done by visual observation, in which it was concluded that highly serially diluted histamine inhibited basophil degranulation. Since histamine at pharmacologic concentrations does exert this effect, the homeopaths (or at least the homeopath to Her Majesty Queen Elizabeth II) again claimed vindication. This led the producers of the BBC's "Horizon" science program to seek advice from a number of people involved in flow cytometry (they even posted a query to the Cytometry Mailing List) on the design of a controlled, blinded experiment in which effects of highly dilute histamine on basophil activation were measured by CD63 upregulation at two institutions in London. A transcript of the program in which results were revealed may be found at <<http://www.bbc.co.uk/science/horizon/2002/homeopathytrans.shtml>>.

Some years back, I attempted to develop a dedicated apparatus for performing BDTs using a cheap green He-Ne laser and Basic orange 21; today, I'd use a red laser and anti-IgE and anti-CD63 antibodies labeled with APC and APC-Cy7. However, there's no guarantee that allergists would run out and buy the gadget; some swear by the test and some don't<sup>3101</sup>. And some still seem to believe that homeopathy works.

### Granulocytes: Eosinophils

People keep asking me about ways of identifying eosinophils. The objective is often to sort live eosinophils without activating them. There are several ways to do this.

Eosinophils are highly autofluorescent, producing strong blue (460 nm) fluorescence on UV excitation<sup>3107</sup> and strong green (525 nm) and yellow (575 nm) fluorescence on blue or blue-green excitation<sup>162</sup>. I have found that they also show some 575 nm autofluorescence on excitation at 532 nm; this is unusual. The original reports on identifying eosinophils based on high autofluorescence date back to the days when fluorescence filters were not very good and when side scatter measurements were not routine. Both of these problems have been corrected in modern flow cytometers and sorters. In my experience, when using 488 nm laser excitation, it is possible to define an eosinophil population in unstained samples by gating on a display of side scatter vs. green (same filter as used for fluorescein) or yellow (same filter as used for phycoerythrin) fluorescence. The green fluorescence is roughly the order of magnitude that would be expected from cells bearing a few thousand molecules of fluorescein, so you might want to try some low intensity fluorescein-labeled beads to make sure your instrument can detect signals in this range.

Once you have a cell sorter, sorting eosinophils can be less costly than sorting many other cell types because no antibody reagents are needed, but the costs of antibodies are, after all, rather low when compared to the cost of the sorter.

Because they contain birefringent granules, eosinophils (at least those from mammalian and avian species) show higher depolarized side scatter signals than do other cells, and can be identified and sorted if one adapts an instrument to measure both polarized and depolarized side scatter (see pp. 278-9 and Figure 7-2)<sup>710,986,3108</sup>.

If you can't live without monoclonals, I will mention that eosinophils, unlike other granulocytes, express CD4 weakly (about at the level of monocytes)<sup>3607,3:09-10</sup>. However, some people seem to think that CD4 expression occurs only on activated eosinophils, while others think CD4 can be detected on all eosinophils, but that levels of expression vary with activation state. The truth could be established easily enough using a PE-Cy5- or APC-labeled anti-CD4 antibody and measuring polarized and depolarized scatter and 488 nm-excited autofluorescence. Unlike neutrophils, eosinophils lack CD16 and express CD49d<sup>3111-2</sup>.

While eosinophils have higher (conventional or polarized) side scatter signals than neutrophils, there is enough overlap between the populations in unfixed preparations to preclude using side scatter as a sole parameter for identification. After aldehyde fixation, the forward and side scatter of eosinophils increases substantially, enabling them to be distinguished from neutrophils<sup>3113</sup>. Fixation or permeabilization also allows acid dyes (such as eosin or fluorescein) to enter the cells and bind to eosinophil basic protein in their granules, which is how the eosinophils got their name in the first place. Fluorescein isothiocyanate is an excellent stain for fixed or permeabilized eosinophils on that account<sup>3114-5</sup>; unfortunately, the basic protein also binds fluorescein and other acid dyes attached to antibodies, resulting in nonspecific staining. If you're interested in blocking nonspecific antibody binding, you might try an acidic molecule that is either nonfluorescent or will not be excited at the wavelength(s) you use for excitation.

### Granulocytes: Neutrophils

#### (Clinical?) Tests of Neutrophil Function

Flow cytometry of appropriate parameters can be used for a variety of **functional studies** of blood cells. Provocative tests of **neutrophil function**<sup>823</sup> may use **tetrazolium dye reduction**<sup>361,820,1611-5</sup> (p.379), **dichlorofluorescein oxidation**<sup>362,1616,8,1620</sup> (p. 379), **dihydrorhodamine 123**<sup>1622-3</sup> (p. 379-80), **membrane potential probes**<sup>823</sup>, or acridine orange<sup>591</sup> or orthogonal scatter measurement of **degranulation**<sup>592</sup>. **Phagocytosis assays**<sup>374,5,1590-9</sup> (pp. 377-8) employ fluorescent microspheres or bacteria<sup>997</sup>.

Seligmann, Chused and Gallin<sup>481</sup> used flow cytometry and DiOC<sub>3</sub>(3) to demonstrate heterogeneity of **membrane potential response** to phorbol esters and chemotactic peptides in neutrophil granulocytes from normal controls and from patients with **chronic granulomatous disease**; their findings were comparable to those others obtained by bulk MP measurements. Studies of patients with chronic granulomatous disease and their families are still done using flow

cytometry, with detection of respiratory burst rather than membrane potential change as the primary marker.

Moving from the granulocytes to their fellow phagocytes, the monocytes and macrophages, I note that Valer et al<sup>172</sup>, using DiOC<sub>6</sub>(3), observed depolarization of guinea pig macrophages after incubation with lymphokines; similar results were reported by others who made microelectrode measurements of membrane potential.

Tests of neutrophil and monocyte/macrophage function are not universally used for clinical purposes. I haven't updated this section, instead electing to recommend a good and fairly recent compendium on the subject, *Phagocyte Function. A Guide for Research and Clinical Evaluation*, edited by Paul Robinson and George Babcock<sup>2396</sup>.

### Neutrophil CD64 in Inflammation and Sepsis

The high affinity Fc receptor for IgG, CD64, is upregulated on neutrophils in inflammation and infection<sup>3116-20</sup>. The fraction of neutrophils expressing CD64 and the level of expression are higher in patients with inflammatory syndromes and sepsis, than in patients with inflammation alone, in pregnant women with eclampsia or infection, or in controls. Bruce Davis <davisb@mmc.org> is pursuing commercial development of a point-of-care CD64 assay for sepsis through his company, **Trillium Diagnostics**. There was only one melody suitable for the following, which I wrote during one of Bruce's presentations on the subject.

#### When I'm Sick – CD64?

When you are healthy, blood PMNs  
Don't need to express  
Sites that tightly bind to Fc gamma, so  
You won't see them when you do flow.  
With inflammation, neutrophils show  
What they lacked before.  
As things get darker, what's the best marker?  
CD64.

Its kinetics can let you know  
When drugs take effect;  
Whether you scan or flow,  
This you can detect.

When tissue's hot, infected or not,  
You will see the change;  
Antigen will not be laid on quite as thick  
If that's not what's making you sick.  
For diagnosis, follow-up, too,  
Who could ask for more?  
It's so specific, it's just terrific-  
CD64.

### Platelets and Megakaryocytes

Ault<sup>1939</sup> has reviewed the general topic of flow cytometry of platelets on several occasions, most recently in

2001<sup>1939,3121-2</sup>; other recent reviews are by Michelson et al<sup>3123</sup> and Shankey et al<sup>3124</sup>.

**Viability and integrity of stored platelets** may be assessed by **dye exclusion** or **membrane potential measurements**<sup>998</sup>. **Platelet activation** can be detected by measurement of **cytoplasmic [Ca<sup>2+</sup>]**<sup>999</sup> or by immunofluorescence analysis of **activation antigens**<sup>1000,1936,1939</sup> such as **P-selectin (CD62p)** and **gp53 (CD63)** or **bound fibrinogen**<sup>1001,1939</sup>. **Anti-platelet antibodies** can be detected using fluorescent antiimmunoglobulin antibodies<sup>998,1939,1962</sup>.

In 1990, Kienast and Schmitz<sup>1937</sup> described staining of what appeared to be immature platelets by thiazole orange; increases in the numbers of such **reticulated platelets** in blood are indicators of thrombopoietic activity<sup>1938-9</sup>. In 1995, Ault and Knowles<sup>3125</sup> used *in vivo* biotinylation<sup>3126</sup> to label all circulating platelets in mice, and showed that reticulated platelets that appeared 24 hours later bore decreased levels of biotin (detected using fluorescent streptavidin), establishing that reticulated platelets are the youngest platelets.

Since the previous edition of this book appeared, increasing attention has been given to the presence and role of **activated platelets in cardiovascular disease**, including myocardial infarction and unstable angina<sup>3122,4,3127-9</sup>. There has also been work on **platelet microparticles**<sup>3122</sup> and on the interactions of platelets and leukocytes. Michelson et al<sup>3130</sup> report that circulating **monocyte-platelet aggregates** are a more sensitive indicator of platelet activation than is P-selectin expression. Platelet activation also results in alterations in **membrane phospholipid packing**, detectable using **annexin V**<sup>3131</sup> (which was used for this purpose some years before its application to the detection of apoptosis) or **merocyanine 540**<sup>3132</sup>; these reagents do not seem to have been widely used for platelet studies.

Thrombopoiesis is the result of the activity of **megakaryocytes**<sup>92-6</sup> in the bone marrow. These cells undergo **endomitosis** as the result of abortive mitosis<sup>3133</sup>, and may have G<sub>0</sub>/G<sub>1</sub> DNA content of 32C or higher, as compared to 2C for other G<sub>0</sub>/G<sub>1</sub> phase cells. Megakaryocyte DNA content is increased in patients with coronary artery atherosclerosis<sup>3134</sup>. Platelets are formed by fragmentation of megakaryocyte cytoplasm; the induction of the fragmentation process appears to involve **nitric oxide**<sup>3135</sup>.

Kuter and Rosenberg and their colleagues<sup>1940-2</sup> made incremental changes in platelet counts in rats by infusion of antiplatelet antibody or by platelet transfusion, and measured the ploidy response of megakaryocytes by flow cytometry, using propidium fluorescence corresponding to 4C or higher DNA content and fluorescein immunofluorescence from antiplatelet antibody as gating parameters. The flow cytometer involved in these studies was a Cytomutt, built at a cost of less than \$20,000. Proportional changes in megakaryocyte ploidy were demonstrated; as the platelet count declined, ploidy increased. Using the megakaryocyte ploidy assay on bone marrow cultures, these workers identified and purified thrombopoietin; expending considerably less man-

power and money than other groups that also isolated this elusive growth factor at about the same time.

The instrument Kuter and Rosenberg used was built shortly before the B-D FACScan became available, and I initially thought they would have been able to use a FAC-Scan or one of the other commercial benchtop cytometers to do their work, but I was told that none of the instruments they tried could keep up with the data rate. Since only 1 of every 1,000 or so cells in the marrow is a megakaryocyte, even in the megakaryocyte-enriched cultures, you have to look at a few million cells to get a DNA histogram from a few thousand megakaryocytes, and the Mutt could evidently run faster than its pedigreed competitors. Shows you how much I know.

### Hematopoietic Stem Cells

In the mid to late 1970's, a period in which most people were content to make single-parameter measurements, a considerable amount of effort and ingenuity was devoted, in a few centers, to the isolation of **hematopoietic stem cells** from animal marrow by multiparameter sorting on the basis of forward and orthogonal scatter, lectin binding, and auto-fluorescence<sup>161,177-9</sup>. The Geneva convention makes it impractical to do the same confirmatory spleen colony assays in man as can be done in the mouse, so flow cytometric approaches to human marrow and stem cell analysis came from different directions.

The emergence of marrow transplantation as a therapeutic procedure for treatment of leukemias, lymphomas, and solid tumors made normal donor marrow as well as pathological specimens more widely available, and flow cytometry has provided a visible and accessible means for the clinical researchers involved in transplantation programs to study the repopulation of the marrow and, at the same time, assess the efficacy of treatment. During the past decade, multicolor immunofluorescence flow cytometry has been used to provide further detail on normal blood cell development in the marrow<sup>288,990,1154,1212,1498,1755-71,3136</sup>; one aspect of this was discussed in detail in connection with leukemia phenotyping on pp. 467-8, which referred to two color illustrations on the back cover.

Over the same period in which flow cytometric immunofluorescence measurements of increasing sophistication were applied to marrow, different investigators extracted increasingly detailed cytokinetic information from marrow samples using DNA content, DNA/RNA, and chromatin structure analysis and BrUdR incorporation. There probably should be some more studies done than have been to date of the **kinetics of subpopulations, defined by immunofluorescence or other additional parameters**<sup>991,1758</sup>, in marrow. The one cell type for which combined DNA and immunofluorescence analyses have been the rule rather than the exception seems to be the megakaryocyte, discussed in the previous section.

At present the isolation of human hematopoietic stem cells is big enough business to keep a number of biotechnol-

ogy companies funded. I picked a few references<sup>1762,1768,1943,61</sup> on flow cytometry and human stem cells out of the then-recent literature for the previous edition; I have picked even fewer out for this one. If you look at any of the older references, you will quickly appreciate that, even a decade ago, stem cell research demanded the capacity to measure as many parameters as flow cytometer manufacturers are willing to make available. That still holds.

Human CD34<sup>+</sup> hematopoietic stem cells are and lack lineage antigens characteristic of more mature cell types. Like rodent stem cells, they have an active glycoprotein pump<sup>1949</sup>, which allows them to be identified by decreased rhodamine 123 retention (p. 376)<sup>1954</sup>. By keeping the concentration of pyronin Y low, and using verapamil to block dye efflux, Srour and his colleagues<sup>2340-2,2627</sup> have been able to use Hoechst 33342 and pyronin Y to define and sort CD34<sup>+</sup> stem cells from various stages of the cell cycle.

Cells capable of initiating hematopoiesis in long-term marrow culture lack CD45R; the primitive erythroid colony forming cells are CD45RO<sup>+</sup>, while most granulopoietic colony-forming cells are CD45RO<sup>-</sup><sup>1947</sup>. T cell precursors and possible lymphoid stem cells express terminal deoxynucleotidyl transferase<sup>1950</sup>. Hematopoietic stem cells can be found and counted in and isolated from peripheral blood<sup>1944,1948,1951</sup>; a higher proportion of peripheral blood stem cells than marrow stem cells express CD33<sup>1948</sup>.

Although CD34<sup>+</sup>HLA-DR<sup>-</sup><sup>1952-3,1957-8</sup> stem cells are more primitive, CD34<sup>+</sup>CD38<sup>+</sup>HLA-DR<sup>-</sup> cells can give rise to multiple cell lineages in liquid culture<sup>1961</sup>. Pluripotent progenitor function has also been associated with a CD34<sup>+</sup>Thy-1<sup>+</sup>Rh123<sup>-</sup>dim cell subset<sup>1954</sup> and with expression of the c-kit ligand receptor<sup>1953</sup>. In 1992, it was reported<sup>1957</sup> that a CD34<sup>+</sup>HLA-DR<sup>-</sup> population could give rise to mesenchymal stromal elements as well as multiple blood cell lineages; this was apparently not the case<sup>1958</sup>, although even more primitive cell populations with such potential are now being studied.

### Clinical Application: Monitoring CD34<sup>+</sup> Stem Cells According to the ISHAGE Protocol

During the past decade, increasing use has been made of CD34<sup>+</sup> **peripheral blood progenitor cells** in autologous and, to a lesser extent, in allogeneic transplantation<sup>3157</sup>. Because these cells normally represent less than 0.1% of the total nucleated cells in blood, it is necessary to use colony-stimulating factors such as G-CSF and GM-CSF to mobilize progenitor cells into the circulation. Counts of CD34<sup>+</sup> cells must then be done to determine the appropriate time for collection. Counts are also useful in following clinical progress of recipients of both marrow and peripheral stem cell transplants; multiparameter flow cytometry has become indispensable for counting CD34<sup>+</sup> cells, and may also assist in the process of detecting and removing residual cancer cells in marrow<sup>1950</sup> or material collected from peripheral blood.

A widely used set of guidelines for CD34<sup>+</sup> cell counting was developed by a committee of the International Society for Hematotherapy and Graft Engineering (ISHAGE, usu-

ally pronounced “ice age”<sup>3138</sup>. The Society has since changed its name to the International Society for Cellular Therapy (ISCT), but the ISHAGE guidelines persist. Stem cells are identified by their CD34<sup>+</sup>CD45<sup>dim</sup> phenotype and forward and side scatter signals in the same range as those of CD45<sup>bright</sup> lymphocytes; 7-AAD staining is used to eliminate nonviable cells from analysis and beads are added to samples to derive an absolute count. Examples of the multiparameter gating procedure as implemented on benchtop analyzers from BD Biosciences and Beckman Coulter can be found online at ISCT’s Web site: <[http://www.celltherapy.org/committees/Committees/Graft\\_Evaluation/graft.htm](http://www.celltherapy.org/committees/Committees/Graft_Evaluation/graft.htm)>.

### Side Population (SP) Stem Cells: Plastic, Fantastic

In 1996, Goodell et al<sup>3139</sup> reported isolation of a population of primitive stem cells from mouse marrow that were distinguished by low Hoechst 33342 fluorescence in the blue (440-460 nm) and red (>675 nm) spectral regions. They subsequently found cells with similar staining characteristics and properties in other species, including humans<sup>3140</sup>. These **side population (SP)** cells are CD34-negative and lineage negative, and appear to have the capacity to differentiate into cell types other than those found in the blood and immune system, e.g., liver and cardiac muscle cells<sup>3141</sup>. Preffer et al<sup>3142</sup> have found cells with the staining characteristics of SP cells in human peripheral blood; these cells, however, do not exhibit the extreme developmental plasticity just mentioned, and, thus far, have only been found to give rise to lymphoid and dendritic cell precursors in culture. SP cells in murine bone marrow are illustrated in Figure 10-17; Goodell has produced a definitive article on their detection<sup>3143</sup>.

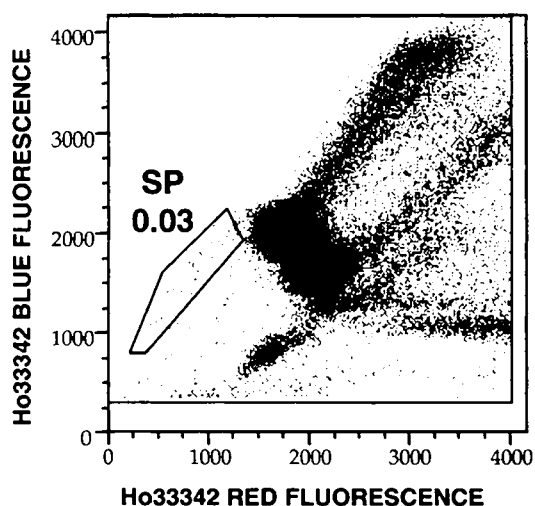

Figure 10-17. SP cells identified on a two-parameter display of blue vs. red Hoechst 33342 fluorescence of cells from murine bone marrow. Courtesy of Margaret Goodell, Baylor College of Medicine.

It was originally thought that Hoechst dye efflux from SP cells might be mediated by p-glycoprotein and/or the multidrug resistance protein MDR1 (p. 376). However, it was established in 2002 that the responsible transporter is from the **breast cancer resistance protein** family; the protein found in murine cells is **Bcrp1**<sup>3144</sup>, while that found in human cells is **ABCG2**<sup>3145-6</sup>. This makes it possible to use fluorescent antibodies to ABCG2, or probes for the gene, rather than Hoechst dye fluorescence, to identify, or confirm the identity of, putative SP cells. The latter approach was taken by Lechner et al<sup>3147</sup>, who described an apparent progenitor cell population in pancreatic islets.

### Immunology

Immunologic applications have almost certainly provided the motivation for purchase of the majority of cell sorters and a substantial fraction of the flow cytometers now in use. The most common application of flow cytometry to immunology involves the detection and quantification, using fluorescently labeled monoclonal antibodies, of **surface antigens characterizing different stages of development of cells of the immune system**. My citation of only a tiny fraction of the tremendous number of publications on this topic<sup>317-22,787-8,794</sup> in previous editions did not stem from a lack of appreciation of the tremendous achievements represented by the development of the reagents and methodology and the elucidation of the pathways of differentiation of the immune system in mice and men. There were and are just too many good papers.

### Immunologic Applications of Flow Cytometry: Still a Growth Industry

Flow cytometry aided in the identification of new surface antigens<sup>907</sup>, in the demonstration of their specificity for particular cell lineages and states of maturation, and in the elucidation of their **receptor function**<sup>908</sup>. Originally, cells found to bear a single antigen were sorted and their functions defined in terms of cell-cell interactions *in vitro*; the trend toward multiparameter analysis and multicolor immunofluorescence studies<sup>909-11</sup> has continued, as has examination of cell function in terms of signaling-related ion fluxes and ion channels<sup>912-3</sup> as an adjunct to the more familiar demonstrations of cytotoxicity, help and suppression. Flow cytometry also continues to be applied to studies of **immune cell activation** by antigens and lymphokines. In fact, the technique is so commonly used in immunology that a significant fraction of papers in the literature in which multiparameter flow cytometry is used in nontrivial ways, but in which the term itself does not appear in the abstract or title, do not get assigned “flow cytometry” as a keyword, and never make it into the MEDLINE database.

The continuing development and commercialization of antibodies, labels, and instruments have made six- and eight-color immunofluorescence available to increasing numbers of users. Last time around, getting the reagents was the biggest problem, even for the relatively small number of people

who had instruments capable of three-color fluorescence measurement. Now, with reagents and instruments in abundance, we have to worry most about making sense of all the data.

In the First Edition of this book, I made particular mention of the **use of cell sorting in isolation and selection of hybridomas and hybridoma variants**, which had been reviewed by Dangel and Herzenberg<sup>549</sup>. I used to see a lot of people use a lot of flow cytometer (and sorter) time screening hybridoma clones, and urged them to consider any possibly more efficient alternative<sup>550</sup>. There are now not only alternatives for hybridoma screening, but alternative sources of monoclonal antibodies, with viruses, bacteria, and fungi now standing in for the human immune system.

In the Second Edition, I singled out an article by Cantrell and Smith<sup>551</sup> on the regulation of T cell growth by the lymphokine interleukin-2 (IL-2), which dealt as much with cell biology as with immunology, as an example of extremely effective use of the technology of flow cytometry and sorting. I am gratified that a substantial fraction of current publications involving flow cytometry in immunology make similarly effective use of the technology, even if I didn't have anything to do with it.

In the Third Edition, I mentioned a nice study by Heagy et al<sup>289</sup>, on the inhibition of immune function by antiviral drugs, including AZT and some others that are routinely given to patients with HIV infection. The paper illustrated some good flow cytometric methodology for looking at lymphocyte activation, by 1994 standards, and, while we have a much more sophisticated repertoire of analytical methods with which to deal study that process today, we don't always make full use of what's available.

### HIV Infection – The “Killer Application”

Clinical flow cytometry wouldn't be what it is today if it hadn't been for the AIDS epidemic. As soon as it was established that the disease was associated with low CD4<sup>+</sup> T cell counts, way too many people went out and bought flow cytometers. Although it has been pointed out that there are a lot of ways in which flow cytometry can be used in the study of HIV infection<sup>280-1,297</sup>, the clinical focus, at least until recently, has been on CD4<sup>+</sup> T cell counting, and on getting the many labs involved with it to do it well enough to make the data usable<sup>282,5</sup>.

Shortly before I wrote the Second Edition of this book, Peter Duesberg<sup>1018</sup> proclaimed that HIV didn't cause AIDS. While very few people agreed with that, the ensuing debate did make it clearer that HIV infection is nothing at all like a typical lytic virus infection, which was the picture initially painted by some virologists who ought to have known better, and not even all that much like some other retroviral infections. As Lewis Thomas suggested, it can be helpful to find out that you didn't know things you thought you knew.

In addition to counting T cells, flow cytometry has proven indispensable for the studies of cellular immunology that are essential to understanding HIV infection. There

have been demonstrations that flow cytometry can be used in a quasi-diagnostic way to detect serum antibodies to HIV<sup>2287</sup>, or to HIV vaccine components<sup>2288</sup>, or to find HIV antigens<sup>2162-5</sup> or mRNA<sup>1403</sup> in cells, but none of these initiatives has led to an accepted clinical test.

When the previous edition of this book appeared, it looked as if correcting altered glutathione metabolism in leukocytes<sup>1117-8</sup> might brighten the grim clinical picture in HIV infection, and some of us worried as to how glutathione measurements could be implemented given that most instruments didn't have the right light sources to excite the best reagents. I cited a then-recent paper by Pantaleo et al<sup>2290</sup> on the immune response to primary HIV infection, in which flow cytometry and PCR assays both demonstrated oligoclonal expansion of CD8<sup>+</sup> T cells, suggesting that cytotoxic cells are involved in clearing the initial viremia. Another interesting paper<sup>2291</sup> suggested that activated CD8<sup>+</sup> cells, i.e., cells expressing CD28 and HLA-DR, are responsible for anti-HIV activity later in the course of the disease. The paper on primary infection was pretty dramatic, not least because most, if not all of the patients studied had had the opportunity to avoid being infected with HIV.

In the years since, **Highly Active Anti-Retroviral Therapy (HAART)** has come on the scene, and patients with access to treatment are feeling better and living longer. We have learned a great deal more about the cellular dynamics of HIV infection, and the developed world seems to have been motivated by the combined forces of compassion, competition, and compulsion to bring programs for prevention, diagnosis, and treatment to the developing world. That's all good news; the bad news is that many people who could easily avoid becoming infected still opt to take their chances.

### Clinical Application: T Cell Subset Analysis

The literature in this area is vast; a lot of the early clinical work with immunofluorescence flow cytometry literature described changes in the **ratios of B- and T cells**, and/or changes in the **ratios of helper/inducer T cells to cytotoxic/suppressor T cells** in various **disorders of immune function**, e.g., **autoimmune diseases** and **immunodeficiency syndromes**. It is clear that what some of us might consider mundane, single parameter immunofluorescence flow cytometry provided researchers and clinicians with a valuable tool for assessment of the function of the immune system.

Things got somewhat out of hand in the few months after the general public became conscious of the existence of AIDS (see p. 99), when a lot of flow cytometers were bought and sold on the faulty premise that subset analysis would be usable as a screening test. As the disease became better understood, it did become clear that the proportion and absolute count of CD4<sup>+</sup>-positive T cells in peripheral blood were useful in following and predicting the clinical course of HIV infection, and attention turned to improving the precision and accuracy with which T cell subset analysis could be done for this clinical use.

As flow cytometry for lymphocyte subclassification first became popular, questions were raised about the equivalence of results obtained by different methods. In particular, it was reported that **Ficoll/Hypaque separation procedures used to prepare mononuclear cells for immunofluorescence analyses caused selective loss of CD8<sup>+</sup> (cytotoxic/suppressor) T cells**<sup>593-4,1002</sup>. Such loss did not occur when leukocytes from whole blood were analyzed, after erythrocyte lysis, with **gating on forward and orthogonal scatter signals used to identify lymphocytes** for purposes of immunofluorescence measurement<sup>175-6</sup>.

The first widely used guideline for immunophenotyping, published by the National Center for Clinical Laboratory Standards (now just NCCLS) in 1992<sup>1876</sup>, recommended the procedure be done on lysed whole blood rather than separated lymphocytes. Subsequent guidelines from the Centers for Disease Control (CDC)<sup>1877-8</sup> and the Division of AIDS (DAIDS), National Institute of Allergy and Infectious Diseases, NIH<sup>1879</sup> also required the use of whole blood lysis.

By the late 1980's, it was recognized that gates set on the basis of forward and orthogonal scatter signals might both exclude some lymphocytes and include other cells, such as monocytes. The **back-gating** technique (see p. 277) was proposed by Loken et al<sup>1251</sup> as a means of determining the purity of the gate and the fraction of the lymphocytes included; the NCCLS standard (revised in 1998<sup>3148</sup>) recommended that the quality of the gate be determined, while the later CDC and DAIDS guidelines made this mandatory.

Many of the problems encountered with determination of **absolute CD4<sup>+</sup> T cell counts** relate to the use of **"dual-platform"** methodology, in which total leukocyte counts and lymphocyte percentages derived from hematology analyzers are used in combination with percentages of CD4<sup>+</sup> lymphocytes derived from fluorescence flow cytometers to calculate absolute counts. It has been established that **"single-platform"** methods, employing only one instrument, produce results with lower variability. Single-platform CD4<sup>+</sup> cell counts can be done on conventional fluorescence flow cytometers if indicator beads at known concentrations are added to samples (see pp. 20-1) to provide cell counts<sup>3149-50</sup>; beads need not be used with instruments that incorporate volumetric sample delivery<sup>3151-3</sup>. A recent report by Bergeron et al<sup>2917</sup> (see p. 448) suggests that sample delivery rates of at least some benchtop flow cytometers are stable enough so that absolute counts could be done by adding beads to only the first and last sample in a run.

Most laboratories in affluent countries now routinely use three- and four-color fluorescence methodology for T cell subset analysis, with CD45/CD3/CD4 staining<sup>3154</sup> providing specific identification of lymphocytes. In a four-color instrument, CD45/CD3/CD4/CD8 staining allows accurate determination of all major T cell subsets in a single tube, as shown on pp. 33-5 and in Figure 1-17 (p. 34). It has been established that laboratories that use CD45 do better on quality assessment studies than laboratories that do not<sup>3155</sup>. The newest revisions of the DAIDS<sup>3156</sup> and CDC<sup>3157</sup> guide-

lines accommodate these recent advances in methodology, but also note that some further modifications in technique may reduce the costs of the procedure.

The April 15, 2002 issue of *Cytometry (Clinical Cytometry)* (Volume 50, Number 2, pp. 39-132) is a Special Issue on "CD4: 20 Years and Counting"<sup>3158</sup>, edited by Frank Mandy.

### T Cell Subsets: Alternative Technologies

A typical benchtop flow cytometer is an expensive instrument, and consumes a substantial amount of power, largely due to its use of an argon ion laser as a light source. Flow cytometer manufacturers have not been completely oblivious to the fact that millions of people with HIV infection live in areas where health care budgets are minimal and practical instruments may need to be run on battery power.

B-D's FACSCount (p. 418), a small, inexpensive flow cytometer intended exclusively for use in T cell subset analysis<sup>2472,3159</sup> was the industry's first effort at developing a CD4<sup>+</sup> cell counter for resource-poor areas. The FACSCount uses a green He-Ne laser source, and reagents (antibodies to CD3/CD4 and CD3/CD8 and counting beads) come in prepackaged tubes. In recent years, a number of systems have been placed in Brazil, India, and Thailand.

George Janossy, in London, working with Debbie Glen-cross in South Africa and Ilesh Jani in Mozambique, among others, felt that flow cytometric CD4<sup>+</sup> T cell counting could be made still more affordable by eliminating counting beads, minimizing reagent costs, and using cytometers with red diode laser sources. Progress along these lines can be assessed as detailed at <http://www.affordcd4.com> as well as in a number of scientific publications.

Sherman et al<sup>3160</sup> had shown in 1999 that CD4<sup>+</sup> T cells could be identified accurately, and adequate counts obtained, by staining only with anti-CD4 antibody and determining the number of CD4<sup>+</sup> cells in a "lymphocyte gate" defined on the basis of forward and side scatter signals. Janossy, Jani, and Göhde<sup>3161</sup>, using a Partec prototype instrument, next demonstrated that CD4<sup>+</sup> T cell counts obtained using **primary CD4 gating**, in which the cells of interest are identified in a two-parameter display of side scatter vs. antibody fluorescence, were equivalent to those obtained using conventional apparatus and multiple antibodies. Anticipating possible problems with sample deterioration in tropical sites, Jani et al<sup>2596</sup> showed that Transfix<sup>2597</sup>, a fixative originally developed by Barnett et al for stabilizing whole blood controls, kept counts stable in samples maintained at 37 °C for as long as three days.

Glen-cross et al<sup>3162</sup> introduced the concept of **PanLeucogating**, using a combination of antibodies to CD45 and CD4 or CD8, to identify the total leukocyte population on a fluorescence flow cytometer, allowing a more accurate CD4<sup>+</sup> cell count to be determined by a dual-platform method; Janossy et al<sup>3153</sup> established the utility of PanLeucogating in single-platform testing using a volumetric instrument.

The Luminex 100 flow cytometer (pp. 431-2), while designed for multiplexed biochemical analyses on beads, has been shown to be usable for CD4+ T cell counting<sup>2447,3163</sup>. The instrument has a volumetric sample delivery system, eliminating the need to use counting beads, and a PanLeucogated CD4+ cell count, using APC- and APC-Cy7-labeled anti-CD45 and anti-CD4 antibodies, can be implemented on a stripped version of the instrument using only the red diode laser and APD detectors.

Partec's Web site (<http://www.partec.de>) documents the incorporation of one of their CyFlow<sup>®</sup> flow cytometers (pp. 427-8) into a mobile laboratory in an SUV with off-road capability; the instrument uses a red diode laser source and identifies CD4+ cells in unlysed blood by single-parameter fluorescence measurements.

Other approaches to more affordable CD4+ cell counts and counters have used techniques other than flow cytometry. Since the number of CD4 epitopes per T cell in HIV-infected individuals is the same as in controls, and remains essentially constant, even with disease progression<sup>1492</sup>, and since there are small or negligible amounts of CD4 present in serum and on monocytes and other blood cells, bulk determinations of CD4 content per unit volume of blood, especially when monocytes have been removed, should provide essentially the same information as counts of CD4-positive T cells. Such assays, which do not require the use of flow cytometers or other expensive instrumentation for readout, were developed by **Zynaxis** and by **T-Cell Sciences**; both the companies and the assays seem to have disappeared.

The IMAGN 2000 instrument<sup>1365,1641</sup> developed by **Biometric Imaging, Inc.** (since acquired by **BD Biosciences**) uses a scanning He-Ne laser and some other technology borrowed from bar-code readers. Sample cartridges contain anti-CD3 and anti-CD4 antibodies labeled with Cy5 and Cy5.5 (p. 336); rotation of the sample cartridge carousel mixes a known volume of unlysed blood with antibodies and introduces stained sample into a capillary of defined volume in which cells are measured; this gives the process the name "volumetric capillary cytometry," although "microvolume fluorometry" is also used. The IMAGN 2000 was found to be an effective single-platform system for CD4+ T cell counting<sup>1484,3164</sup>, although precision for low counts was suboptimal. The IMAGN 2000 could be, and was, adapted fairly easily to do other cytometric chores, predominantly associated with **blood banking**<sup>3165-76</sup>. However, BD abruptly decided to stop selling (and, apparently, stop supporting) the system; this had little impact in the CD4+ counting world but left several blood bankers I know unhappy. Rumors that the IMAGN 2000 will be resurrected persist, but Elvis is still out of the building.

A couple of years ago, I prodded a number of people in academia and industry, all involved in the development of cytometry technology, to consider how today's technology could be applied to develop a small, rugged, inexpensive CD4+ T cell counter. The most interesting response came

from Arjan Tibbe, then a doctoral student working at the University of Twente, in the Netherlands, under the direction of Jan Greve and the late Bart DeGroot, and collaborating with Leon Terstappen of **Immunicon**. Arjan designed and tested a prototype instrument called the "EasyCount," based on imaging technology; in my opinion (and I do not have any financial interest in this instrument), it represents the most promising approach to doing reliable and economical CD4+ T cell counts and, perhaps, a number of other cell assays, in both resource-poor areas and the developed world, where health care costs could also do with some reduction.

Arjan's thesis work, also done in collaboration with Leon Terstappen, involved the development of a small, simple, laser scanning cytometer, the **CellTracks**<sup>™ 2383,4096-9</sup>, now being commercialized by Immunicon for rare cell detection (p. 470). The CellTracks system uses disposable cartridges with an observation window featuring a series of deposited nickel lines. Cells tagged with antibodies bound to ferrofluid nanoparticles are introduced into the chamber, which is then placed in a magnetic yoke, aligning the antibody-tagged cells between the nickel lines, facilitating scanning (Immunicon's observation chambers and magnetic yokes are available from Molecular Probes in their Captivate<sup>™</sup> product line, as is ferrofluid-conjugated streptavidin). While the CellTracks, which uses a red diode laser as a primary light source, can perform two- and three-color immunofluorescence analyses, including CD4+ counts, the objective of the EasyCount design exercise was to produce an even simpler system, ideally one with no moving parts.

The EasyCount is basically a low-power imaging fluorescence microscope, with illumination from a blue LED. A whole blood sample is mixed in a disposable plastic chamber with acridine orange, which renders all the nucleated cells intensely fluorescent, and with biotinylated anti-CD4 antibody and ferrofluid-conjugated streptavidin. The observation chamber (which, unlike the CellTracks chamber, does not have nickel lines on its surface) is then placed in the magnetic yoke, which draws cells bearing a relatively high density of antigen (meaning all of the CD4+ T cells and some monocytes) to the top of the chamber. The microscope, which operates at a low enough magnification so that focus adjustment is not needed, makes a fluorescence image of most of the viewing area on a CCD chip of the type used in relatively inexpensive digital cameras; software programmed into the chip allows the cells in the viewing area to be identified and counted, allowing the CD4+ T cell count to be calculated from the initial volume of blood used and the percentage of the chamber area in the field of view. The field of view is large enough to permit counting enough cells to keep the precision of the count at better than 10% when the number of circulating CD4+ T cells is as low as 200 cells/microliter. The count takes about a minute. The EasyCount is about the size of a toaster, but consumes much less power; it can be run for hours on batteries. It has no moving parts, requires minimal operator training (pipetting

sample and reagent are about all that is required of the operator), and can be manufactured for around \$1,000, meaning that it could be sold at a profit for \$5,000, which is less than many hospitals in developing countries are paying for fluorescence microscopes which they now use to do substantially less accurate and precise CD4+ counts with Dynal's magnetic beads<sup>3177</sup>. The consumable/reagent costs for EasyCount will probably be under \$1. The EasyCount can also do a total leukocyte count, using an anti-CD45 antibody instead of the anti-CD4 antibody, and probably can also do a total lymphocyte count, using a cocktail of anti-CD3, anti-CD19 or CD20, and anti-CD56 antibodies, allowing calculation of the percentage of CD4+ T cells among lymphocytes.

What the EasyCount does is essentially a primary CD4-gated CD4+ T cell count; its results should therefore be expected to be comparable to those obtained using this methodology in flow. George Janossy and Frank Mandy are now looking retrospectively at some flow cytometric data to determine whether primary CD4-gating produces results equivalent to PanLeucogating or gating based on both CD45 and CD3 staining, and I suspect this will turn out to be the case. There may be some suggestion that this strategy will work in the forthcoming version of the CDC guidelines for CD4+ T cell counting, which Frank Mandy has helped develop. The World Health Organization is now funding construction of several EasyCount systems for clinical testing. For information, e-mail lterstappen@immunicon.com.

Because the EasyCount, like ChemoMetec's NucleoCounter (p. 448), examines cells that are brightly stained, relatively short observation times can be used even though the LED illumination sources are of relatively low intensity. A somewhat more adventurous approach to a simple CD4+ cell counter was recently described by William Rodriguez and Bruce Walker of Harvard Medical School, working in collaboration with John McDevitt at the University of Texas<sup>3178</sup>. This group developed a number of microfluidic devices intended to perform low-cost biochemical assays in HIV patients; an initial effort at extracting information on CD4+ counts by measuring soluble antigen has led to work on an imaging counter that identifies CD4+ cells based on the fluorescence of bound labeled anti-CD4 antibody.

Small, simple imaging counters with low associated instrument and reagent costs, such as those just described, should be usable in the many areas of the world in which HIV infection is prevalent and in which there is not a reliable supply of clean drinking water, let alone sheath fluid. If, as I expect, these instruments provide the same information as is now provided at higher cost by flow cytometers, it won't be long before activism and/or budgetary constraints bring the more cost-effective technology to the developed world. I'm sure we'll find other things to do with our flow cytometers; I'm also sure we'll find low-cost scanning and imaging methods for doing some of those other things. Ultimately, that should leave us with a few pennies more to spend on other areas of research and patient care.

## Clinical Application: Transplantation

Horsburgh et al<sup>3179</sup> have recently reviewed the applications of flow cytometry to histocompatibility testing.

Before fluorescence flow cytometry existed, it was established that the presence of antibodies against donor cells in the serum of a kidney transplant recipient greatly increased the likelihood that the organ would be rejected. Crossmatching developed to detect such antibodies in potential recipients initially were based on the detection of lysis of donor cells by complement in the presence of recipient serum. However, this method failed to detect recipient antibodies that did not fix complement, and the presence of such antibodies was also associated with an increased likelihood of rejection.

In 1983, Garovoy et al<sup>1880</sup> developed the **flow cytometric crossmatch**, in which recipient serum is mixed with donor cells; antidonor antibodies are detected by staining the cells (typically, separated T cells, which do not normally bear immunoglobulins on their cell surfaces) with a fluorescent antihuman immunoglobulin reagent. Subsequent studies<sup>1881</sup> have shown that flow cytometric crossmatching can be more sensitive than the conventional method, particularly in high-risk recipients, e.g., those in whom grafts have previously failed, and continue to confirm the predictive power of the flow crossmatch<sup>3180</sup>.

Flow cytometric crossmatches are now done using two color fluorescence techniques to identify T or B or other specific donor cell types<sup>1888</sup>. Wang, Terashita, and Terasaki<sup>1889</sup> reported that the use of platelets as target cells reduced the false positive rate, but Terasaki platelets evidently did not become as popular as Terasaki plates. Wetzsteon et al<sup>1890</sup> developed flow cytometric methods to discriminate cytotoxic from noncytotoxic antibodies, improving sensitivity and specificity. Talbot et al<sup>1891</sup> recommend the addition of HLA-DR matching to the flow cytometric crossmatch, while Lazda<sup>1892</sup> reported that a strongly positive B cell crossmatch identifies a high-risk subset of patients. Scornik et al<sup>1893</sup>, in a 1994 evaluation of flow crossmatching, noted needs for improved methods of measuring B cell antibodies and quantification of T cell antibodies; Berteli et al<sup>1894</sup> described a procedure to determine the specificity of anti-B cell antibodies. The need for quantification has been met, at least to some extent, using materials and methods discussed on pp. 354-9.

**One Lambda, Inc.**, a company founded by Paul Terasaki, produces the **FlowPRA**<sup>®</sup> line of assays for **panel-reactive antibodies** that allow flow cytometry to detect the presence of antibodies to HLA Class I and/or II antigens; the reagents are beads, each of which bears an individual antigen. It should be fairly obvious that this type of analysis is ideally suited to multiplexing, and, indeed, One Lambda has licensed Luminex's technology and offers both color-coded antibody-bearing beads<sup>3184</sup> and its own private-labeled instrument, the **LABScan**<sup>™</sup> 100. Flow crossmatching against

## TIME COURSE OF EVENTS IN T LYMPHOCYTE ACTIVATION

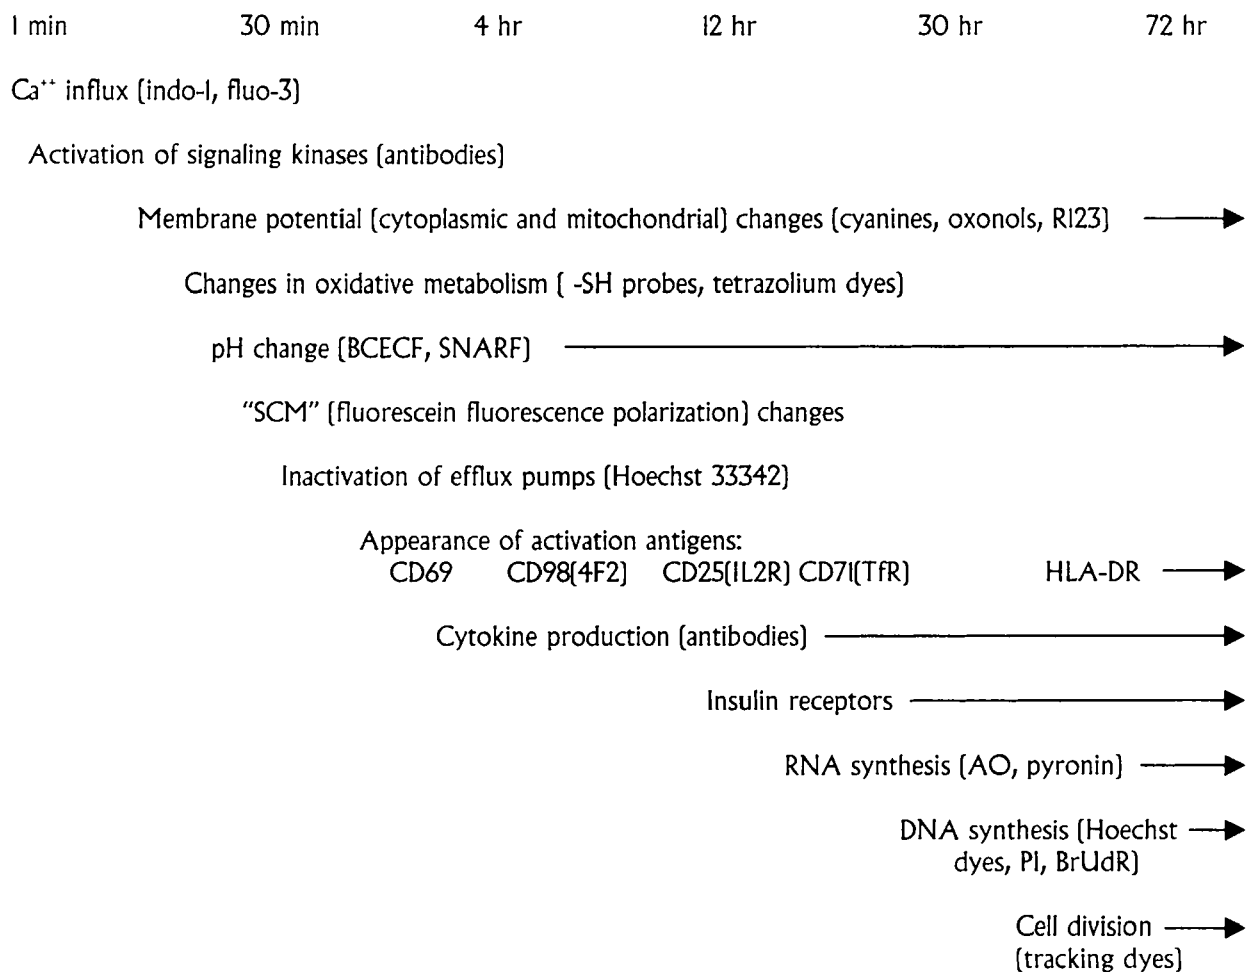

Figure 10-18. Time course of events in T lymphocyte activation and probes for their cytometric detection.

beads seems to have become popular; however, while most patients who reject transplanted kidneys have anti-HLA antibodies<sup>3185</sup>, monitoring antibody levels by FlowPRA is not sensitive for diagnosis of early rejection<sup>3186</sup>.

Other flow cytometric techniques have been used with success for diagnosis of **graft rejection**. In 1981, Cosimi et al<sup>1003</sup>, at the Massachusetts General Hospital, reported that changes in T cell subset ratios could be used for monitoring renal transplant recipients, with a rise above 1.0 in the (CD4<sup>+</sup>)/(CD8<sup>+</sup>) ratio indicating an impending rejection episode. This finding did not apply to some other populations, even in Boston; at the time, I was collaborating with Terry Strom, then at the Brigham and Women's Hospital, where a much less stringent immunosuppressive regimen was in use. The ratio of (CD4<sup>+</sup>)/(CD8<sup>+</sup>) cells in patients at the Brigham was often greater than 1.0 in the absence of evidence of rejection; we accordingly looked at DNA synthesis in T cell subpopulations in an attempt to detect the lymphocyte acti-

vation we expected should occur during a rejection episode. We found<sup>604</sup> that an increase in the number of S/G<sub>2</sub>/M phase CD4<sup>+</sup> cells predicted a rejection episode, while an increase in the number of proliferative CD8<sup>+</sup> cells did not. We<sup>605-6</sup> and others<sup>1895</sup> thus turned our attention to means of detecting lymphocyte activation, for diagnosing rejection and for other purposes as well.

More recently, Yu et al<sup>3187</sup> have studied the leukocyte count and differential count in urine post-transplant as a predictor of renal graft rejection; Stalder et al<sup>3188</sup> proposed the use of markers of activation as a monitor of immunosuppressive therapy, after finding fewer indicators of activation in immunosuppressed graft recipients than in normal controls.

#### Detecting Lymphocyte Activation

There continues to be considerable interest in the development of **flow cytometric measures of lymphocyte acti-**

vation, both for basic research and for clinical purposes which include tissue typing and organ matching for transplantation, evaluation of cellular immune response, assessment of the activity of autoimmune disease processes, and monitoring of transplant recipients for early signs of graft rejection. Detection of activated T cells is perceived as providing a more precise indication of the dynamics of immune function, in these contexts, than could be obtained simply from counting absolute or relative numbers of different lymphocyte types in the blood. Figure 10-18 shows the time course of a number of events in T lymphocyte activation that may be observed by flow cytometry, and lists some probes that might be used in each case.

### Foundations: From PHA (the Lectin) to PHA (the Pulse Height Analyzer)

When the previous editions of this book appeared, much of our understanding of lymphocyte activation was based not on the real thing, but on a convenient surrogate model, i.e., polyclonal cell activation by mitogenic lectins, such as phytohemagglutinin (PHA) and concanavalin A (con A) or antibodies, e.g., anti-CD3, which reacts with the constant region of the T cell receptor.

When I was a medical student at New York University in the early 1960's, the people who were most excited about PHA were the geneticists. When the lectin was added to peripheral blood, lymphocytes started dividing, providing numerous mitoses in which chromosomes could be counted and, to some extent, identified; chromosome banding, on which classification is now based, had not yet been developed. Cytogenetics itself was in such a sorry state that it was not established until after PHA came into use that the normal human chromosome complement was 46 and not 48 chromosomes.

Within a couple of years, it was discovered that certain antigenic preparations, such as tuberculin, could act as mitogens, but only when the lymphocytes to which they were added came from individuals who would exhibit delayed hypersensitivity skin responses to subcutaneously injected antigen. In 1964, Fritz Bach and Kurt Hirschhorn, then at N. Y. U., discovered that lymphocytes from two different individuals would, when mixed, proliferate; they noted that such a **mixed lymphocyte reaction (MLR)** could provide an *in vitro* test of histocompatibility<sup>607</sup>.

Lymphocyte activation, whether by mitogens or antigens, has, since the 1960's, been detected and quantified by bulk measurements of the incorporation of **tritiated thymidine** (<sup>3</sup>H-TdR), which is taken as an indication of the number of cells in a sample involved in **DNA synthesis**, i.e., the number of activated lymphocytes. Since DNA synthesis does not occur for some 30-36 h following lymphocyte stimulation, no indication of cell activation can be obtained either from <sup>3</sup>H-TdR uptake or from flow cytometric assessment of changes in DNA content at points earlier in the time course of the process. Lectin-activated and, later, mitogenic antibody-activated cells became widely used as a model

for activation because the lectins commonly used stimulated most peripheral blood lymphocytes, that is, almost all of the T cells, making it possible to detect stimulation using <sup>3</sup>H-TdR within 48 hours, while, when lymphocytes were stimulated by antigens or in an MLR, a much smaller fraction of the population was activated, with the result that it was necessary to wait for many generation times, typically, 5-10 days, until the number of proliferating cells in the culture became large enough to be detectable by <sup>3</sup>H-TdR incorporation.

In the late 1960's, Fred Valentine and others at N.Y.U. followed proliferation of antigen-stimulated cells by **time-lapse cinematography**<sup>2943-4</sup>. It's hard to argue with these data; they revealed a mean doubling time of 12 h with the shortest time between 2 divisions of a given cell and its daughters being 8.5 h. <sup>3</sup>H-TdR uptake data demonstrated a doubling time in incorporation of about 10 to 12 hours, in the same ballpark. Under appropriate conditions, most cells entering the proliferative phase continued to divide for 3-5 days.

By the mid 1970's, it had been established, although it was not widely appreciated, that flow cytometry of **DNA content** at 30-36 h could detect smaller activated cell populations than would be detected at this time by isotope incorporation<sup>595-6</sup>. Also, Darzynkiewicz and his coworkers<sup>262-3, 597-600</sup> and others<sup>601</sup> showed that **increases in RNA content in mitogen-stimulated lymphocytes**, detectable by increased metachromatic fluorescence of acridine orange (AO) (Figures 3-10, p. 97, and 7-16, p. 321), preceded increases in DNA content, occurring as early as 12 hours following exposure to mitogens. This established elevated RNA content as an indicator of lymphocyte activation, but only among the relatively small number of immunologically oriented users of flow cytometry who were amenable to looking at anything but immunofluorescence. It was not until 1980 that Noronha, Richman and Arnason<sup>602</sup> used DNA/RNA flow cytometry to demonstrate the presence of activated lymphocytes in cerebrospinal fluid (CSF) from patients with active multiple sclerosis; the number of activated cells they found increased with the activity of the disease, while no activated cells were found in CSF from control patients free of inflammatory neurologic disease. I assumed, at the time, that the publication of this work in *The New England Journal of Medicine* would get more attention than it seems that it did.

### Functional Probes for Activation

The 1970's and 1980's saw the development of probes and methods, flow cytometric and otherwise, for measurement of **functional parameters**, such as membrane microviscosity, structuredness of cytoplasmic matrix, membrane-bound and **cytoplasmic [Ca<sup>2+</sup>]**, **pH**, and **membrane potential**. As was mentioned in the discussion of these areas in Chapter 7, changes in many functional parameters were found to occur within a few minutes to an hour following lymphocyte exposure to mitogens, which prompted me and

my colleagues<sup>112,474,484</sup> and others<sup>417-9,493,603,1896<sup>7</sup></sup> to attempt to detect early T cell activation by flow cytometry using functional probes. Results to date have generally not been reliable enough to permit routine clinical application of such assays. At present, the most tractable functional parameter available for detection of lymphocyte activation seems to be **membrane potential**<sup>484,493</sup>; it is possible to demonstrate apparent cytoplasmic and mitochondrial hyperpolarization in activated cells at 5-12 hours, thus providing some improvement in speed of detection as compared to RNA fluorochromes.

I say "apparent" hyperpolarization because the increased staining with cyanine dyes or rhodamine 123 may also be affected by the decrease in **P-glycoprotein efflux pump activity** that occurs within a few hours of T cell activation (see p. 309). The role of P-glycoprotein in lymphocytes is discussed in several papers in a 2003 issue of *Clinical and Applied Immunology Reviews*<sup>3189-94</sup>. Although P-gp may provide an indicator of lymphocyte activation, it does not appear to play a key role, as evidenced by the fact that activation proceeds normally in P-gp-deficient mice.

**Unfortunately, membrane potential/efflux, pH, and [Ca<sup>2+</sup>] measurements, have the distinct disadvantage of requiring cell samples that are not only viable, but also what I have called "happy," for analysis.**

Despite the technical difficulties involved, flow cytometric studies of lymphocyte activation using physiologic probes kept some of us hooked for many years, on the basis that, when our ships came in, we would be able to detect stimulated lymphocytes in the first few minutes after they responded to surface ligand binding. This, in turn, should have given us all kinds of wonderful tests that we could use both to elucidate mechanisms of ligand-receptor interactions and to assess the quality of cell function for clinical purposes.

When I started playing around with membrane potential-sensitive dyes, I had the conviction that I was about to encounter blinding flashes of truth rather than blinding headaches. However, the more I (and others) worked in this area, the more confused things seemed to get. For example, Tsien et al<sup>426</sup>, based on membrane potential estimation using oxonol dyes, reported that concanavalin A hyperpolarized mouse thymocytes; Taki<sup>456</sup>, using microelectrodes, my colleagues and I<sup>424</sup>, using DiOC<sub>6</sub>(3) and flow cytometry, and Kiefer et al<sup>425</sup>, using a radiolabeled cation, had described a depolarizing effect of lectins on mouse and human lymphocytes.

Felber and Brand<sup>465</sup> resolved this apparent discrepancy when they reported that hyperpolarization of thymocytes arises from activation of a Ca<sup>2+</sup>-dependent K<sup>+</sup> channel. This channel is fully activated in resting lymphocytes, and therefore cannot produce increased K<sup>+</sup> flux and the resulting hyperpolarization in response to lectin stimulation. They believed that the slight depolarization they observed in con A-stimulated lymphocytes was due to Na<sup>+</sup> influx, which occurs by nonelectrogenic as well as by electrogenic pathways<sup>466</sup>.

This may also help explain the puzzling variations in the magnitude of the early lectin effects on MP in rat and human T cells which I have noted, and which have been observed by practically everyone to whom I have spoken who has looked at MP in such cells.

Further clarification of interactions between cytoplasmic [Ca<sup>2+</sup>], pH, and membrane potential came from the work of Grinstein et al<sup>1910-5</sup>. Thymic lymphocytes possess Ca<sup>2+</sup>-sensitive K<sup>+</sup> channels, which are activated by moderate increases in intracellular [Ca<sup>2+</sup>], resulting in hyperpolarization. At higher [Ca<sup>2+</sup>], nonselective cation channels open, producing depolarization. Variations in the levels of intracellular [Ca<sup>2+</sup>] in various earlier studies could explain some discrepancies.

The situation appears to be different in B cells. Monroe and Cambier<sup>480-2</sup>, using flow cytometry with DiOC<sub>6</sub>(3), consistently observed membrane depolarization in mouse B cells after reaction with multivalent (cross-linking) anti-immunoglobulin (anti-Ig), which is mitogenic for these cells. Monovalent Fab fragments of anti-Ig neither cross-link nor depolarize the cells; such fragments are not mitogenic. Depolarization of the cell membrane by raising [K<sup>+</sup>]<sub>o</sub> does not stimulate B cells to reproduce, but does lead to increased expression of Ia antigen, an activation response also produced by cross-linking surface receptors with anti-Ig.

With Terry Strom, I used DiOC<sub>6</sub>(3) and flow cytometry to demonstrate different responses of T and B cells to lectins<sup>484</sup> and cholinergic agents<sup>485</sup>. Ken Rosenthal and I demonstrated different patterns of MP change following Epstein-Barr virus addition to cells having and lacking receptors for the virus<sup>486</sup>. The problem is that you have to be careful and lucky to get experiments like this to work, and the same is true when you do pH and calcium studies, which may be one of the reasons there is so much controversy and inconsistency in the literature.

Membrane potential probes would not have been of great use to us for detection of early activation responses even if the magnitude and direction of potential changes had been consistent, because the fluorescence distributions obtained from cells labeled with cyanine or oxonol dye probes, even when normalized using a size-dependent scatter or extinction signal (Figure 7-28 p. 389), were too broad to permit discrimination of small subpopulations of activated cells. None of the membrane potential probes available today could improve the quality of flow cytometric membrane potential measurements sufficiently to solve this problem.

We had much better luck with membrane potential measurement later in activation, i.e., 5-12 hours and more after stimulation. We could consistently demonstrate apparent hyperpolarization, probably due in large part to increased mitochondrial activity, using either cyanine dyes or rhodamine 123 (see Figure 7-30 and pp. 395-7). However, these dyes provided essentially the same information as could be obtained using pyronin Y to stain RNA at 20 hours, and the latter dye, unlike the membrane potential probes, could be used on fixed cells.

We next turned our attention to probes that could be used for ratiometric measurements of functional parameters. While preliminary experiments with ratiometric pH measurement, using carboxyfluorescein as an indicator with dual-wavelength excitation (Figure 7-35, p. 406), suggested that early changes occurred in stimulated T cells, the literature of the mid-1980's contained conflicting reports of cytoplasmic alkalinization and acidification occurring in lymphocytes in response to mitogenic stimulation<sup>427,521,870,871</sup>. Later work by Grinstein indicated that calcium-dependent acidification is the dominant response<sup>1912</sup>, but that alkalinization can occur as a result of activation of Na<sup>+</sup>/H<sup>+</sup> by a calcium-independent mechanism<sup>1913</sup>. Intracellular pH, like membrane potential, turned out to be a sideshow; calcium remained in the center ring<sup>1914,5</sup>.

### DNA, RNA and Activation Antigens

By the time indo-1 became available, permitting ratiometric measurements of cytoplasmic [Ca<sup>2+</sup>] to be done by flow cytometry, my colleagues and I, having become increasingly frustrated in our attempts to tame flow cytometric functional probe measurements of cell activation, had, instead, started to collaborate with other investigators, who, using bulk methods and single-parameter immunofluorescence flow cytometry, were trying to characterize **activation antigens**, which appeared on, or increased dramatically on, lymphocytes within hours following mitogenic stimulation. This led to studies in which **combinations of DNA (and RNA, and sometimes membrane potential) stains and fluorescent antibodies were used to demonstrate early and late activated T cells** in clinical and experimental contexts.

We first approached the problem of detecting activated inducer and cytotoxic/suppressor cell populations, respectively, by examining DNA content in inducer and cytotoxic/suppressor populations defined by staining with anti-CD4 and anti-CD8 antibodies<sup>604</sup>. The clinical interest underlying these experiments related to prediction of graft rejection (p. 494).

We next looked at lectin-<sup>605</sup> and alloantigen-<sup>606</sup> activated T cells to determine the **kinetics of appearance and the distribution of several activation antigens**, i.e., antigens that appear on the surfaces of cells only after mitogenic stimulation. We found that all proliferating cells, including those in G<sub>1</sub>, bore the **transferrin receptor (TfR, now CD71)**, the **4F2 antigen**<sup>1898,1916-7</sup> (now CD98), and the **Tac antigen**, which is the **interleukin-2 receptor (IL2R, now CD25)**. The IL-2 receptor was detectable on stimulated cells at 8-12 hours; Redelman and Wormsley<sup>1004</sup> subsequently showed, using fluorescein immunofluorescence and pyronin Y staining, that IL-2 receptor appearance precedes increases in RNA content following lymphocyte stimulation, and is not affected by inhibitors of RNA synthesis.

The 4F2 (CD98) antigen was detectable on the surfaces of stimulated T cells as early as 4 h after exposure to lectin or antigen; the transferrin receptor (CD71) and HLA-DR were

not detectable on the majority of activated cells until somewhat later. In the case of HLA-DR, simultaneous staining with Hoechst 33342, pyronin Y, and fluorescein-labeled antibody revealed that a substantial fraction of proliferating cells, identifiable by their increased RNA and DNA content, were not expressing HLA-DR. We found increased display of 4F2 antigens in peripheral blood lymphocytes taken from a transplant patient during an acute rejection episode; the number of cells bearing 4F2 diminished to normal levels following successful treatment with monoclonal antibodies.

We evaluated several parameters, including 4F2 and CD25 antigen expression, measured 12-24 h after initiation of mixed lymphocyte reactions (MLRs)<sup>607</sup>, to determine whether these could serve as indicators of activation. The percentages of cells bearing either of these antigens at 12-24 h correlated well with measurements of thymidine incorporation made at 120 h. Also, removal of activated cells from mixed lymphocyte cultures by treatment with anti-CD25 antibodies and complement at 48-72 hours largely abolished proliferative responses otherwise detectable by thymidine incorporation at 96-120 hours; it thus seems likely that those T cells bearing 4F2 or CD25 activation antigens early in the activation process are the specifically activated T cells which are destined to proliferate later.

In order to demonstrate that flow cytometric immunofluorescence analysis could be made accessible and affordable, we showed<sup>303</sup> that 4F2 antigen on stimulated lymphocytes could be detected by measurements of the fluorescence of allophycocyanin (APC)-conjugated antibody in a flow cytometer using a 7 mW helium-neon laser source; this, however, failed to produce a massive demand for such instruments.

Biselli et al<sup>1899</sup> used dual color flow cytometry to study the kinetics of several activation antigens on CD4<sup>+</sup> and CD8<sup>+</sup> subsets after 24, 48, 72, 120, and 168 hours' incubation with PHA and Con A. Expression of these molecules followed a consistent time-course with no major differences between subsets. CD69<sup>1918</sup> expression peaked at 24 hours, whereas CD25 and CD71 expression peaked at 48 and 72 hours, respectively.

The expression of CD45RA remained stable for 72 h and then briskly decreased with no major differences between PHA and Con A activation; this presumably reflects the parallel increase in CD45RO expression which occurs with the conversion of T cells from the "naive" to the "memory" state following activation<sup>1900,2</sup>.

As contrasted with functional probe assays of activation, measurements based on detection of activation antigens do not require live, let alone "happy," cells, and the physical presence of a newly synthesized or newly expressed protein on the cell surface provides a much more comfortable and substantial basis for clinical decision making than could ever be obtained from constant, let alone inconstant, ephemeral changes in ionic concentrations.

Since this work was done, a large number of studies (far too many to cite) have been published in which the state of

activation of lymphocytes *in vivo* was assessed by measurement of a single activation antigen. I would suggest that this is not always a good idea, because different patterns of expression of activation antigens may be observed in response to different antigenic stimuli. For example, Santamaria et al.<sup>1919</sup> found that CD69 was selectively expressed only on CD8<sup>+</sup> T cells infiltrating rejecting human heart allografts, while both CD4<sup>+</sup> and CD8<sup>+</sup> cells expressed CD25.

I would argue that **increased RNA content** and **transferrin receptor (CD71) expression** (see Figure 10-7 and pp. 460-1) are the parameters best suited to serve as "gold standards" for activation processes that can reasonably be expected to have been ongoing for 20 hours or more, *in vivo* or *in vitro*. Measurements of these parameters, unlike those of DNA content, identify cells in the G<sub>1</sub> as well as the S, G<sub>2</sub>, and M phases of the cell cycle.

Pyronin Y, an effective stain for RNA, can be used in conjunction with Hoechst 33342 and, presumably, with DRAQ5 as vital DNA stains, and with antibodies labeled with fluorescein and with PE-Texas Red and/or PE-Cy5 tandem conjugates, allowing the state of activation to be delineated in immunologically defined cell subpopulations. Without such multiparameter experiments, it is not clear which activation antigens are the most trustworthy indicators in any particular situation; it would be foolish to expect that any given measurement, RNA content included, could be optimal in all contexts.

The transferrin receptor, CD71, is present on all proliferative phase cells, and can be detected on the surfaces of living cells by fluorescent antibody staining; I see little reason to use the Ki-67 antibody, which requires permeabilization and appears to stain the same cells.

When human peripheral blood mononuclear cells are stimulated with polyclonal mitogens such as PHA or sepharose-conjugated CD3 antibody, at least 60% of the T cells in both the CD4<sup>+</sup> and CD8<sup>+</sup> subpopulations typically express activation antigens; this degree of activation is readily detectable by <sup>3</sup>H-TdR incorporation after only 3-4 days, even though most cells do not initiate DNA synthesis for at least 30 hours after stimulation<sup>1903</sup>. Although as many as 2% of the lymphocytes in an unstimulated culture may be activated due to previous natural exposure of the host to antigens, this background activated population is negligible in the context of analysis of mitogen-stimulated cultures.

### Mitogen Response versus Antigen Response

Studies of mitogen responsiveness may be useful in the context of demonstrating generalized immune deficiencies, such as occur in HIV infection<sup>1904</sup> and in some cancer patients (see pp. 383-5). However, in research applications, and in analyses of clinical situations in which successful therapy depends on restoration or generation of specific immune responses, notably treatment of AIDS<sup>1905</sup> and cytokine/cell therapy of cancer<sup>1906,7</sup>, the cytometric assay strategy differs from that used in studies of activation induced by polyclonal mitogens.

In an alloantigen-stimulated culture or MLR, a much smaller fraction of lymphocytes, typically 0.5-1.5% of the population, is initially activated than is the case in a mitogen-stimulated culture. Detection of activation by incorporation typically requires at least 5-6 days in culture, by which time several doublings of the activated cell population have occurred; since the population of naturally activated cells is approximately equal in size to the population specifically stimulated by alloantigen, it is necessary to demonstrate a significant increase over background to detect specific activation, especially when a cytometric assay is done before proliferation of the alloantigen-stimulated population has occurred. We found that the chi-square test, applied to data from 5,000- to 10,000-cell samples, could discriminate between a match, a single-allele mismatch, and a two-allele mismatch in MLRs analyzed for 4F2 (CD98) or CD25 antigen 12-24 hours after stimulation.

The frequency of cells that recognize a specific bacterial or viral antigen, however, can be much lower than the frequency of responding cells in an MLR. In adults tested at least 20 years after primary infection with varicella-zoster virus, it was found<sup>1904</sup> that only 1/105,000 cytotoxic T lymphocytes (range 1/13,000 to 1/231,000) specifically recognized a viral protein. This suggests that proliferation would typically have to multiply the number of cells initially activated by antigen by a thousandfold to create a population of specifically responding cells roughly the same size as the background activated population. The mean generation time of cycling stimulated adult human lymphocytes is between 12<sup>2943,4</sup> and 20 hours<sup>1903</sup>; multiplying the original activated population by 1,024 could take as long as 10 days. The frequency of cells recognizing antigen in a recently immunized population may be considerably higher than the frequencies reported above. Waag et al.<sup>1909</sup> reported that proliferation at 5 days induced by *Francisella tularensis* antigen in lymphocytes taken from human volunteers 14 days after immunization with a live vaccine strain exceeded that induced by con A.

Stimulation by **superantigens**, such as **Staphylococcal enterotoxin B (SEB)**, is restricted to those T cells with V $\beta$  regions of the T cell receptor that can be crosslinked by the antigen; thus, while the fraction of responding cells in an SEB-stimulated culture will vary with the pattern of V $\beta$  expression (SEB reacts with human V $\beta$ 3, 12, 14, 15, 17, and 20), this fraction will almost always be lower than the fraction of responding cells in a PHA-stimulated culture, and SEB is often used as a positive control stimulus in assays designed to measure stimulation by antigen.

In the situation in which immunization is expected to have occurred long ago, and in which there has not been recent challenge, frequencies of specifically activated cells on the order of 1/100,000 make it difficult for flow cytometry to detect specifically activated cells against the background activated population before substantial antigen-induced proliferation occurs. However, several advances made since the previous edition of this book was published facilitate the

task, and have wider implications for the general field of immunology, as well.

### Detecting Activation by CD69 Expression

The CD69 antigen<sup>1918,3195-8</sup>, a surface receptor involved in kinase-mediated signaling and present in most blood cell types, including basophils, eosinophils, mast cells, and platelets, is expressed within 1-4 h of mitogenic or antigenic stimulation of T lymphocytes; expression in mitogen-stimulated cultures peaks at 24-48 h<sup>1899</sup>, and the antigen is reported to be diluted by successive cell divisions.

In 1995, Maino et al<sup>3199</sup>, at B-D, reported that early CD69 expression was detectable in lymphocytes stimulated with the comitogenic antibodies CD2 and CD2R, with pokeweed mitogen, with SEB, and with *Candida albicans*, and that the fraction of cells expressing CD69 at 4 h tracked <sup>3</sup>H-TdR uptake at 3 d in cultures stimulated with various doses of comitogenic antibodies. B-D later introduced the **FastImmune™ Activation System**, of reagents, which include an anti-CD69 antibody and gating antibodies appropriate for detection of activation in T, B, and NK cells. Lim et al<sup>3200</sup> suggest that quantitative, as well as quantitative, determination of CD69 expression may be useful in detecting activation.

Craston et al<sup>3201</sup> found that stimulation by mitogens resulted in the most rapid expression of CD69 on both T and NK cells, while alloantigen-stimulated cells responded more slowly. Caruso et al<sup>3202</sup> studied expression of CD25, CD69, CD71, and HLA-DR on T cells from healthy individuals stimulated with different mitogens and antigens; CD69 was the earliest expressed antigen, while HLA-DR was the latest. However, regardless of the stimulus used, lymphocytes expressing CD25 and CD71 were always more numerous than cells expressing CD69 and HLA-DR. Variations in the proportion of CD4+ and CD8+ T cells expressing each marker were observed with different stimuli. Activation marker expression showed overall agreement with <sup>3</sup>H-TdR uptake in discriminating between positive and negative responses, but the percentages of marker-positive cells were not correlated with amounts of <sup>3</sup>H-TdR uptake. Low doses of mitogens and antigens and/or short exposure times could induce activation antigen expression that was not followed by proliferation.

Hutchinson et al<sup>3203</sup>, studying HIV-negative individuals with immunodeficiencies, found that most showed CD69 expression in response to mitogen, although <sup>3</sup>H-TdR uptake was diminished or absent. Sieg et al<sup>3204</sup> reported that, after anti-Vβ3 Ab stimulation, CD4+Vβ3+ cells from HIV-infected patients expressed CD69 and CD25, but demonstrated defects in expression of cell cycle-associated proteins, D-type cyclins, and cyclin A that precluded cell cycle progression. The proliferation defect was most apparent in patients with diminished CD4+ T cell numbers and higher plasma HIV RNA levels.

Thus, it appears that some caution is required in the use of CD69 expression as an indicator of T cell activation; I

have said that CD69 is aptly named, because, while it may be sexy, it has little to do with reproduction.

### Cytokines: Detecting Activation and More

CD69 expression is, however, a good marker of cells capable of **cytokine production**, which itself is an indicator of activation. Around the time the previous edition of this book was written, immunologists were seriously contemplating widespread use of ELISA measurements of cytokine production in 96-well plates in hopes of detecting a return of immune function in patients treated for HIV infection. The idea alone was enough to strike terror into the heart of anyone who remembered how hard it had been to get the dozens of labs involved in AIDS clinical trials to produce reasonably consistent CD4 counts.

Cytometry came to the rescue. Accumulation of cytokines in the Golgi apparatus of stimulated T cells permeabilized with paraformaldehyde and saponin had been observed by fluorescence microscopy in the late 1980's<sup>3205,8</sup>; by the early 1990's, several groups<sup>3209-16</sup> were developing and refining flow cytometric procedures for cytokine detection. The subject of cytokine detection<sup>2703</sup> was addressed briefly on pp. 357-8.

In 1993, Jung et al<sup>3211</sup> introduced the use of the ionophore **monensin** to block transport of cytokines out of the Golgi apparatus, increasing fluorescence signals. In 1994, Vikingsson et al<sup>3213</sup> reported that the number of interferon-γ (IFN-γ)-positive cells in cultures correlated with IFN-γ levels measured in culture supernatants. In 1995, Picker et al<sup>3215</sup> reported using **phorbol 12-myristate 13-acetate (PMA)** and **ionomycin** as an accessory cell-independent stimulus and **brefeldin A** to block transport out of the Golgi apparatus, and Prussin and Metcalfe<sup>3216</sup> demonstrated the specificity of intracytoplasmic cytokine staining by showing that staining could be blocked by excesses of cytokine or unlabeled antibody.

In 1997, Mehta and Maino<sup>3217</sup> combined staining for cytokines with staining for BrUdR incorporation to demonstrate that those cells that still synthesize cytokines at 48-72 h after stimulation have undergone cell division.

In 1997, Waldrop et al<sup>3218</sup> described modifications of the cytokine assay procedure that made it possible to identify **antigen-specific T cells**. Cells were incubated with antigen and accessory cells in slant tubes, and brefeldin was not added until 1 h after stimulation was initiated to prevent its possible interference with antigen processing. Anti-CD28 antibody was added as a costimulator, and anti-CD69 antibody was used to identify responding cells. The refined assay was used to study frequencies of response to various pathogens of CD4+ memory/effector cells from HIV+ patients. Further refinements described by Suni, Picker, and Maino<sup>3217</sup> in 1998 allowed the assay procedure to be performed on whole blood, eliminating the need for isolation of mononuclear cells. **BD Biosciences** now offers cytokine assays as part of its **FastImmune™** product line, which includes an antiCD28/antiCD49d costimulatory reagent.

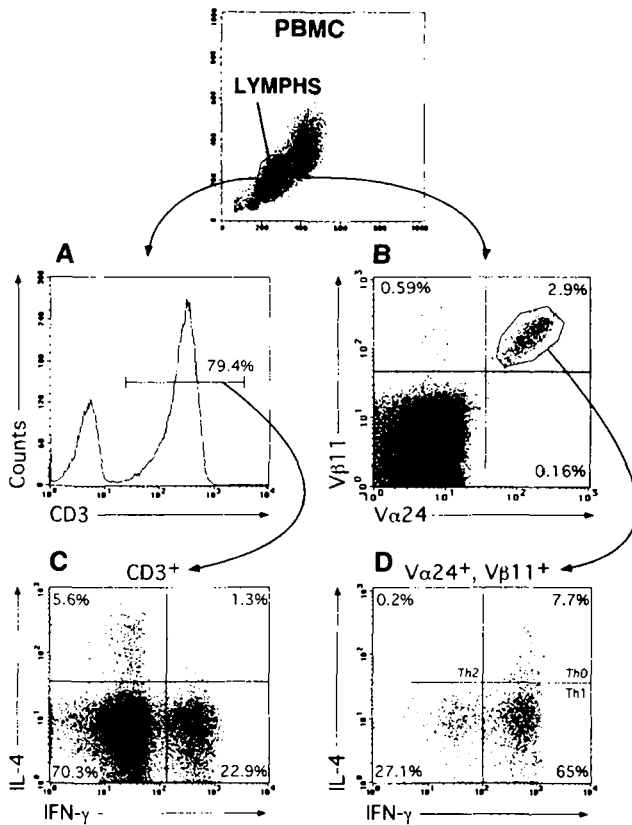

Figure 10-19. Intracellular cytokine staining. Courtesy of Calman Prussin, NIAID.

Intracellular cytokine staining is illustrated in Figure 10-19, provided by Calman Prussin of the National Institute of Allergy and Infectious Diseases. Human peripheral blood mononuclear cells were activated with PMA/ionomycin. Parallel samples were stained with either fluorescein-antiCD3 (panels A, C) or fluorescein-antiV $\beta$ 24, PE/Cy5-anti V $\beta$ 11 (panels B, D) in addition to the cytokine antibodies, APC-antiIFN- $\gamma$  and PE-anti IL-4. The populations shown in panels A and B are from the lymphocyte scatter gate in the top panel. CD3-positive T cells from panel A, represented in panel C, show a typical staining pattern for IFN- $\gamma$  and IL-4 (C) demonstrating the simultaneous use of these mAbs to differentiate Th1, Th2, and Th0 cells. A small subset of T cells expressing the V $\beta$ 24, V $\beta$ 11 TCR, shown in the gate in panel B, are seen in panel D to have a unique pattern of cytokine expression. Numerical values in panels A and B represent positive cells as a percentage of total lymphocytes; values in panels C and D represent percentages of gated cells. Marker placement was determined from identical cell samples preincubated with unlabeled anti-cytokine antibodies.

### Ins and Outs of Cytokine Staining

Following PMA/ionomycin stimulation, CD4 antigen is internalized and subsequently replaced. In the presence of brefeldin A, this does not occur; CD4 $^{+}$  cells typically lose about 90% of detectable CD4It is therefore standard proce-

dures to stain cells for CD8, setting a gate around the more intensely stained CD3 $^{+}$  cells to define the CD8 $^{+}$  T cell population and another around the unstained CD3 $^{+}$  cells to define the CD4 $^{+}$  population. Hennessy et al<sup>3220</sup> examined several anti-CD4 antibodies and determined that BD's Leu3a/3b multiclone reagent alone allowed direct identification of the CD4 $^{+}$  subset in PMA-stimulated cells. Intracellular cytokine measurements have recently been discussed by Pala and Hussell<sup>3221</sup> and by Prussin and Foster<sup>3222</sup>.

Although intracellular cytokine staining is probably adequate for assay purposes, it is desirable under other circumstances to be able to demonstrate cytokine production by living cells, allowing them to be sorted on the basis of their expression patterns. This was made possible in 1995 by Manz et al<sup>2704</sup>, who developed a cell surface affinity matrix that allowed capture of secreted cytokines, which could subsequently be detected with fluorescent anti-cytokine antibodies. The original technology (p. 360) involved biotinylation of cell-surface proteins and attachment of streptavidin-conjugated anti-cytokine antibodies; subsequently, the procedure has been simplified by use of bispecific antibodies made by conjugating an anti-CD45 antibody with an anti-cytokine antibody<sup>2705,3223-5</sup>. These are commercially available from Miltenyi Biotec. Although CD69 and cytokine expression can be used, as described above, to identify antigen-specific cells, cell surface affinity matrix staining for cytokines can also be combined with tetramer staining, permitting even more precise definition of specificity<sup>2705,3225</sup>.

### Tetramer Staining: Talking the Talk; Walking the Walk?

Tetramer staining<sup>2359-64,3225</sup> to detect T cells reactive with defined peptide sequences was introduced on pp. 47-8. Although it has been possible to isolate at least some specifically reactive B cells by staining with fluorescently labeled antigen<sup>1107,3226-7</sup>, T cells normally "see" antigen only after it has been processed by antigen-presenting cells, and antigen alone will not bind strongly to the T cell receptor. However, fluorescently labeled tetrameric complexes of antigenic peptides with MHC class I or II  $\alpha$  chain and  $\beta_2$ -microglobulin mimic the processed antigen and its presenting cell well enough to be used to identify antigen-specific T cells. Since the initial description of tetramer staining of antigen-specific CD8 $^{+}$  T cells by Altman et al<sup>2359</sup> in 1996, the protein engineering technology has been refined<sup>3228-30</sup> and the application of the technique has yielded a great deal of previously unobtainable information. Since I don't have the time and space to devote to an extensive review, I will cite a short but informative one by Kelleher and Rowland-Jones<sup>3231</sup>.

While tetramer staining is exquisitely specific, it defines a structural and not a functional characteristic of the cell<sup>3212</sup>. Virus-reactive T cells from patients with HIV infection may lack their expected cytolytic function, and fail to proliferate in response to antigenic or mitogenic stimulation, and similar functional defects have also been noted in tumor-specific T cells from cancer patients<sup>3231</sup>. In the era of 11-color flow

cytometry, the obvious thing to do is combine tetramer staining with measurements of functional parameters, as noted in the previous section.

### Tracking Dyes: Activation and Ontogeny

In the previous edition of this book, I predicted that tracking dyes such as PKH26 would be enormously useful in following cells through generations. I had noted the 1990 finding by Weston and Parish<sup>1542</sup> that cells covalently labeled with carboxyfluorescein succinimidyl ester (CFSE) retained label for weeks, but not the 1994 publication by Lyons and Parish<sup>3233</sup> in which CFSE was used to study division of lymphocytes. As can be seen from Figures 7-23 and 7-24 and pp. 371-4, there is a big difference between PKH26 and CFSE. Using a mathematical model, one can derive information about the proliferation of a cell population using either label, but, while it is usually possible to discern peaks representing different generations of CFSE-labeled cells by visual inspection of a one-or two-parameter histogram<sup>2349</sup>, it is rarely or ever possible to do so in the case of PKH26-labeled cells. It is also possible to get sharper peaks in a CFSE fluorescence distribution by starting with an input cell population sorted from a narrow region of the fluorescence peak representing the first generation<sup>2350,3234</sup>. Lyons et al<sup>3249</sup> and Parish and Warren<sup>3235</sup> have recently reviewed CFSE methodology. Hasbold and Hodgkin<sup>3237</sup> have shown that isolated nuclei from CFSE-labeled cells retain enough of the dye to permit discrimination among different generations, allowing expression of nuclear antigens, BrUdR incorporation, etc. to be followed through successive generations of cells in otherwise homogeneous populations.

It should be obvious that tracking dye labeling provides a relatively easy method of isolating antigen-responsive T cells; label the cells, add antigen and whatever accessory cells and factors are necessary, and, after five or six days (or more), sort out the cells with very dim dye fluorescence; these will be the cells that have divided several times in response to the antigenic stimulus. Easy, and practical, but, as it turns out, that's not all. Keeping track of generations turns out to provide a great deal of interesting information about lymphocyte differentiation in a very graphical form. It is simple to determine, from two-parameter displays, whether the expression of a particular antigen or antigens or the production of a particular cytokine or cytokines differs from one generation of cells to another. This type of analysis has produced a substantial body of evidence that many developmental processes in both T and B lymphocytes are **division-linked**, or **division-regulated**<sup>3237,48</sup>.

The original CFSE work was done in Australia, and the technique caught on there before it spread to the rest of the world. I wasn't paying much attention until I made my first visit to Australia in 1998. I've been keeping up since, but here I am busy writing while other people are doing the experiments I wanted to do.

### What is "Early" Activation (Trick Question)?

It should now be obvious that, if we're willing to wait a few hours, we have a lot of different ways of detecting specific activation of lymphocytes. What can we do if we want to look at the first few minutes of the activation process?

There are the fast functional parameters; cytoplasmic  $[Ca^{2+}]$  is one that comes to mind, as are pH change and "structuredness of cytoplasmic matrix" (pp. 383-5), which, because it is less well understood, harder to measure, and widely regarded as unreliable, is a definite dark horse. Carl June, who probably has had as much experience with flow cytometric calcium measurements as anyone<sup>866,7,1714,5189,67,1920</sup>, made a case<sup>1897</sup> that they could be clinically useful, but it hasn't happened yet.

If we're willing to settle for not keeping the cells alive, we can look at **kinases**. Figure 10-9, on pp. 468-9, came from the *tour de force* paper by Perez and Nolan<sup>3000</sup> in which 11-color flow cytometry was used to determine the phosphorylation states of several different kinases in different T cell subsets; speed was not the object. However, Chow et al<sup>3249</sup> have shown that it can be, as illustrated by Figure 10-20.

Antibodies to phosphotyrosine<sup>1631,2</sup> were used by Far et al in 1994<sup>1632</sup> to define the overall level of protein phosphorylation in cells; since then, it has been possible to produce antibodies to both phosphorylated and nonphosphorylated forms of a number of kinases. Such antibodies are available from a number of sources; most of those used by Perez and Nolan<sup>3000</sup> and those used by Chow et al<sup>3249</sup> came from **Cell Signaling Technology**.

Figure 10-20 shows levels of phosphorylated extracellular signaling related kinase (**ERK1** and **ERK2**) in human peripheral T cells activated by various doses of PMA or (bottom right panel) by crosslinking anti-CD3 bound to the T cell receptor. Note that a substantial increase in phosphorylation, compared to control values, is detectable within 3 minutes after stimulation.

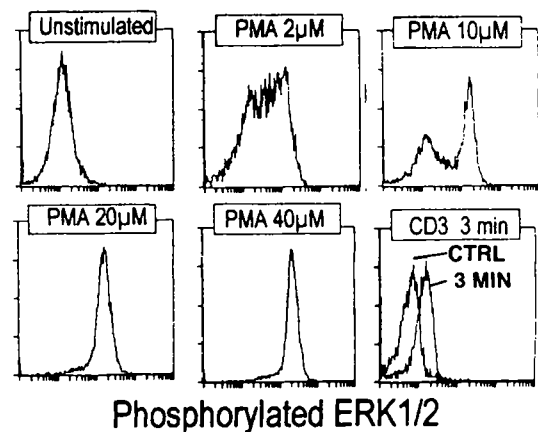

Figure 10-20. ERK1/2 phosphorylation in T cells exposed to various activation stimuli. From: Chow S et al, *Cytometry (Commun Clin Cytom)* 46:72-8, 2001 (reference 3249), © John Wiley & Sons, Inc. Used by permission.

So we can detect, or think we can detect, activation at 3 minutes by a change in kinase phosphorylation, although there is a hefty overlap between the histograms representing control and stimulated cells. So far, so good, but what flow cytometry can't tell us is whether there is temporal heterogeneity in kinase responses in cell populations.

Image analysis studies on calcium concentration changes in single lymphocytes over time done by Wacholtz and Lipsky<sup>1735</sup> revealed a considerable heterogeneity in both the magnitude of increases in intracellular  $[Ca^{2+}]$  and in the lag time before increases occurred, even when cells were stimulated with anti-CD3 or PHA, which are presumably reacting with more or less the same structures on all responsive cells.

If we define a proliferative state, or at least a state in which the cells tell us they're thinking about proliferating by synthesizing RNA, as a definitive indicator of activation, we have to determine whether the cells in or on which we find a putative "early" indicator of activation, such as a calcium flux change or kinase phosphorylation, get as far as the proliferative state. In the studies of CD25 and 4F2 expression on lectin stimulated cells and in MLRs to which I referred previously, this was done; antibody/complement lysis of cells expressing these antigens eliminated the normal proliferative response. In at least some situations, however, it is established that cells that respond to ligands with an increase in calcium flux do not necessarily go on to proliferate.

When cells react with real antigens, the reaction is between the antigen and a variable region of the cellular receptor, implying that different clones of cells with different binding constants for any particular antigen may behave differently. This could conceivably translate into a broad spectrum of lag times in the small fraction of cells which do react with antigen to a great enough degree to manifest ion flux responses, display activation antigens, and proliferate, and it is not at all clear that all those that do the first thing do the second, etc. There is obviously some kind of threshold that must be crossed before specific activation occurs, but it may be crossed at different rates by different cells; in some recent talks I've given, I've compared the cells to personal computers, with the most reactive cells analogous to the Pentium and Power PC processors, the slightly slower ones, to the 486 and 68040, and so on, down to the slowly reacting 8088 and 68000 cells, and to the Z-80 and 6502 cells, which don't react. All but the last group run the program, but the different groups run it at different speeds.

From studies with activation antigens, we know that the most active cells will express CD25 and 4F2 within 12 hours following stimulation. However, if you lyse cells in an MLR, which exemplifies specific antigenic stimulation, 48 hours after initiation of the reaction, you don't eliminate all proliferation at 120 hours; you have to do the lysis at 72 hours to completely wipe out the culture. Since it is unlikely that cells make it all the way to DNA synthesis without at least transiently expressing CD25 and 4F2, this suggests that some cells in an MLR don't get to the "early" stage of activation at which they express CD25 and 4F2 until 60 hours or so after

initiation of the culture. In other words, "early" isn't the same time for each cell.

It would be good to be able to separate the "early early" cells from the "late early" cells, in order to define both the chemical characteristics of their respective receptor-antigen interactions and any differences in their biologic behavior in immune responses *in vivo*. The most obvious way to do this may be by sorting proliferating cells from different generations using CFSE.

I realize that I haven't gotten into some other parameters that change during lymphocyte activation, such as oxidative metabolism (lymphocytes seem to do a mini-respiratory burst, complete with bioluminescence), or even the size change, or "blast transformation," which can be detected in flow cytometers just as it can under the microscope. But the bottom line is that we now have the hardware, the reagents, and the data analysis techniques needed to use flow cytometry productively to investigate real immune reactions instead of lectin stimulation, and we can go looking for activated cells in patients with HIV infection, or cancer, or chronic fatigue syndrome<sup>2286</sup>, or post transplant.

## Cancer Biology and Clinical Oncology

This represents another area in which the body of literature is so large that it is impossible to take a representative sample without writing another book. In the Second Edition, I cited a few then-recent reports<sup>965-72</sup> to try to exemplify the range of things being done with flow cytometry in the field. I itemized the following for the Third Edition:

Ornitz et al<sup>966</sup> used DNA flow cytometry to follow ploidy changes in the precancerous state and in neoplasia of pancreatic cells which occur in transgenic mice expressing SV40 T-antigen.

Tough and Chow<sup>967</sup> sorted high- and low-IgM natural antibody-binding populations from a heterogeneous lymphoma line and found that the level of antibody binding correlated inversely with tumorigenicity.

Kenter et al<sup>968</sup>, using multiparameter flow cytometric analysis found differences in colcemid susceptibility between tumorigenic and nontumorigenic lymphocytes, in the process defining a cell cycle phase they called G1', intermediate between G<sub>0</sub> and G<sub>1a</sub> and absent in immortalized and tumorigenic cells.

Cook and Fox<sup>969</sup>, using ADB, examined intracellular pH regulation in CHO cells subjected to hyperthermia at normal and acidic pH, and found that internal pH was regulated under both conditions, ruling out a disturbance of pH homeostasis as a mechanism for the thermosensitization observed at low pH.

Ota et al<sup>970</sup> observed that a glycoside from ginseng which inhibits growth of and induces melanogenesis in B16 melanoma cells, increased the number of peanut agglutinin binding sites on the cell membrane, while another glycoside, which induces melanogenesis but does not stimulate growth, does not change lectin binding patterns, although both compounds decreased membrane fluidity.

Other membrane effects of differentiating agents were studied by Fibach et al<sup>971</sup>, who found that DMSO or hexamethylene-*bis*-acetamide decreased uptake of fluorescent fatty acid derivatives by murine erythroleukemia cells.

Bucana et al<sup>972</sup> studied uptake of hydroethidine in neoplastic cells; unoxidized hydroethidine could be distinguished from its oxidation product, ethidium, and quantified in cells not only by flow cytometry, but by bulk fluorimetry of microtiter plates.

When I wrote the last edition, the reviews on flow cytometry in oncology already written by others<sup>586,608-9,906,980-2</sup> covered the territory effectively and let me get off with my usual barbed commentary.

This time around, I have not done an exhaustive review of either the cancer research or the clinical oncology literature, so I will simply mention a few items I've run across, making no attempt at anything like thorough coverage of either field.

### Cancer Diagnosis: Cervical Cytology

Considering that a good deal of the development of flow cytometry was paid for by agencies and companies interested in **automating the cytologic diagnosis of cervical cancer**, it may seem surprising that no flow cytometric clinical instrument for this purpose has yet emerged. However, pathologists, not entirely without reason, like to work with samples they can see and keep. As far as I know, there is only one FDA-approved automated cervical cytology screening instrument on the market; it is the **FocalPoint<sup>TM3250</sup>** (formerly **AutoPap<sup>®</sup>**), made by **TriPath Imaging, Inc.** (Burlington, NC; <http://www.tripathimaging.com>). TriPath Imaging was formed by the merger of two companies active in the development of automated Pap smear screening, **NeoPath** and **AutoCyte**, and acquired the intellectual property of a third, **Neuromedical Systems**. Both TriPath Imaging and **Cytec Corporation** (Boxborough, MA; <http://www.cytec.com>) make apparatus for preparing high-quality slides from cervical cytology specimens; Cytec is, or at least was, also working on an automated screening system. The predecessors of automated screening instruments were computerized microscope systems that facilitated presentation well-prepared of slides to cytotechnologists and cytopathologists.

The FocalPoint and its now-extinct competitors are/were imaging systems that examine(d) slides stained with Papanicolaou stain, and, whenever I have spoken or written about this subject in the past, I have lamented the fact that nobody seemed to be developing a system for cervical cytology screening that looked for some more specific markers associated with cell proliferation.

Well, such a system has finally been developed by **Molecular Diagnostics, Inc.** (Chicago, IL; <http://www.molecular-dx.com>) and is on the path toward FDA approval. The **InPath<sup>TM</sup>** system apparently uses fluorescently labeled antibodies to the **transferrin receptor (CD71)** and/or the **epidermal growth factor receptor (EGFR)** as an indicator

of cellular dysplasia or neoplasia<sup>325-2</sup>, plus a nuclear stain (?DAPI) and a fluorescent antikeratin antibody selective for cervical cells. An additional test detects antigen(s) produced by the human papilloma virus (HPV), infection with which predisposes to the development of cervical cancer. Slides treated with the fluorescent reagents can later be stained with Papanicolaou stain. It will be interesting to see whether the system catches on.

Flow cytometry does, apparently, have some contribution to make to cervical screening; it is reported that forward and side scatter signatures can be used to assess the adequacy of a cervical specimen prior to slide preparation<sup>3254</sup>. Now, if you just throw the DNA stain and the antibodies into the mix, who knows what might happen?

Exfoliative cytology using flow cytometry has also been applied to monitoring the treatment of superficial bladder cancer by DNA or DNA/RNA analysis of bladder irrigation specimens<sup>906</sup>. In at least one urology department, an argon ion laser was used both to pump a dye laser for tumor phototherapy and as a light source for a flow cytometer to monitor the therapy.

### DNA Content Measurements Yet Again

The earliest uses of flow cytometry in oncology dealt with analyses of **abnormalities of DNA content in tumor cells** and with **perturbation of the cell cycle by chemotherapeutic agents**. It was learned rather quickly that anything that kills cells will perturb the cell cycle sooner or later, and this line of research got less interesting with time. The demonstration of abnormalities in DNA content, on the other hand, provided and continues to provide prognostically relevant, objective bases for classification of tumors arising in many different tissues. At least one Cytomutt was used effectively and successfully<sup>1008</sup> in a surgical department in an institution in which the commercial instruments and their proprietors in the pathology department were absorbed by immunology and not very interested in DNA.

DNA analysis was improved considerably by mathematical modeling to minimize the effects of debris and clumps; Kallioniemi et al<sup>2277</sup> described a fully automated histogram analysis procedure which preserves the strong predictive power of the corrected aneuploid S-phase fraction. The issue of quality control of DNA analysis has also been addressed<sup>2048,2278</sup>; it was noted on pp. 25-6 that DNA ploidy and S phase fraction in breast cancer, once routinely measured and then abandoned<sup>2320</sup>, can add prognostic information when appropriately determined<sup>2321</sup>.

The development of a procedure permitting DNA content analysis of nuclei from **paraffin-embedded specimens**<sup>610</sup> made it possible to analyze large numbers of specimens from cases in which outcomes were already known; once they didn't have to wait for outcomes of 10-year prospective studies before they could publish, a lot more pathologists got interested in doing DNA flow cytometry. A few new wrinkles and improvements in the basic flow cytometric technique have been described<sup>3254-7</sup>. However, pa-

thologists, as previously noted, still feel more comfortable with slides than with flow. John Crissman and his colleagues in Detroit (personal communication) put together their own static system, as did other groups of pathologists who probably would have been scared to build flow cytometers, and they could do DNA by fluorescence with precision almost as good as that obtainable from flow cytometers. Commercial systems for the purpose are now available; CompuCyte's Laser Scanning Cytometer, developed by Lou Kamensky himself<sup>2047</sup> seems to have established a niche here<sup>3258-60</sup>.

A Research News article by Rachel Nowak<sup>2294</sup> in the 24 June 1994 issue of *Science*, headlined "A New Test Gives Early Warning of a Growing Killer" described work by Brian Reid, Peter Rabinovitch and others at the University of Washington<sup>2296-9</sup> on factors that determine the likelihood that an individual with Barrett's esophagus will develop esophageal cancer. One is p53 gene mutation; a second is aneuploidy. According to Nowak, "More DNA means a brighter glow, which is detected by an instrument called a flow cytometer." The aneuploid cells are not necessarily malignant, but increasing aneuploidy suggests progression to cancer within a period of 18 months to 7 years. Survival of patients who have undergone surgery after early detection of progression is projected to be 80% at 5 years; 5-year survival in esophageal cancer has historically been under 5%. The Washington group has kept up its work on Barrett's esophagus<sup>3261-4</sup>, identifying increased numbers of cells with 4N (G<sub>2</sub> or tetraploid) as an additional predictor of progression.

This brings to mind an interesting series of papers published in the late 1980's<sup>3300-3</sup> in which flow cytometric DNA analysis was adapted to detect hyperdiploidy in cultured dermal fibroblasts, which occurs in individuals genetically predisposed to cancer of the colon and nasopharynx, among other sites. The aneuploidy here isn't even a premalignant change, since it is occurring in cells of a completely different line from those that become malignant.

There isn't even universal agreement about how cells become aneuploid; they may undergo a second round of mitosis without cell division, becoming tetraploid and then losing chromosomes<sup>2304-5</sup>, or they may go through cycles of unbalanced mitosis<sup>2306</sup>. Cell lines which undergo megakaryocytic differentiation make good model systems in which to study polyploidization<sup>2307</sup>; Mouthon et al<sup>2308</sup> published a study on one such line which included some very nice flow cytometry; also see p. 487.

Aneuploidy due to chromosomal instability precedes the development of colon cancer in patients with **ulcerative colitis**<sup>3265</sup>; Clausen et al<sup>3266</sup> sorted diploid and aneuploid cells from a colectomy specimen and subjected them to comparative genomic hybridization to analyze gene alterations.

### Beyond DNA Content: Antigens, Oncogenes and Receptors, and Response to Therapy

DNA or DNA/RNA content measurements and analyses of chromatin structure have been applied to classification and estimation of prognosis of leukemias, lymphomas<sup>3267</sup>,

and solid tumors<sup>979</sup>. It is virtually certain that strong correlations exist between DNA (and RNA) content and proliferative activity of tumors, on the one hand, and surface antigen patterns, on the other; while, early in the game, different investigators emphasized different parameters, many more people now appreciate the utility of multiparameter measurements.

The appreciation that various **oncogenes** are expressed in many human cancers has led to the development of flow cytometric techniques for detecting oncogenes, initially by immunofluorescence of antibodies directed against gene products<sup>1012-4</sup>, later with genetic probes. A paper by Stål et al<sup>2279</sup> on simultaneous analysis of DNA and *c-erbB-2* expression in breast cancer exemplifies the technique; an article by Winter et al<sup>3268</sup> discusses the influence of the antiapoptotic **Bcl-2** gene on the proliferative activity of lymphomas<sup>3268</sup>.

Jacobberger et al<sup>3269-73</sup> have applied multiparameter flow cytometry to analyses of interactions between oncogenes, growth factors, and receptors in several experimental systems.

Interest remains in determination of **drug sensitivity** of tumor cells. Detection of drug efflux using functional probes or antibodies, glutathione measurements, etc., at least for now, typically mean simply that chemotherapy, whatever the agent, is likely to be ineffective. *In vitro* drug sensitivity testing of bacterial pathogens is useful only because some drugs work and some don't; in most types of cancer, where no drugs work, drug sensitivity testing, cytometric or otherwise, is pointless. However, both flow and static cytometry may be useful in assessing response to various modalities of therapy; to chemotherapy, we must now add immunotherapy<sup>3274</sup> and, eventually, gene therapy<sup>3274</sup>.

Chow et al<sup>3249</sup> (see pp. 501-2 and Figure 10-20) and Jacobberger et al<sup>3300</sup> have developed flow cytometric methods for determination of **kinase activities** in cells; these can be applied to detection of inhibition of kinases by drugs. The latter paper<sup>3300</sup> documents specific detection of the activity of **STAT5** in chronic myelocytic leukemia (CML) cells and lines expressing **Bcr/Abl**, and inhibition of STAT5 by **imatinib (STI-571; Gleevec)**, now a first line therapy for CML.

### Immunophenotyping in Hematopathology

As immunologists adopted flow cytometry as a research tool for studying the differentiation and function of lymphocytes, immunofluorescence analysis was applied to the black sheep of the lymphocyte family, cells from leukemias and lymphomas, and such phenotyping was found to provide clinically relevant information. Although relatively few tumor specific antigens have been found, the demonstration on tumor cells of different antigens characteristic of various developmental stages in the tissue of origin provides information not only about the lineage, but also about the probable biologic behavior of the tumor<sup>1009</sup>.

Immunophenotyping of leukemias, lymphomas, and other hematopoietic neoplasia is widely enough used for

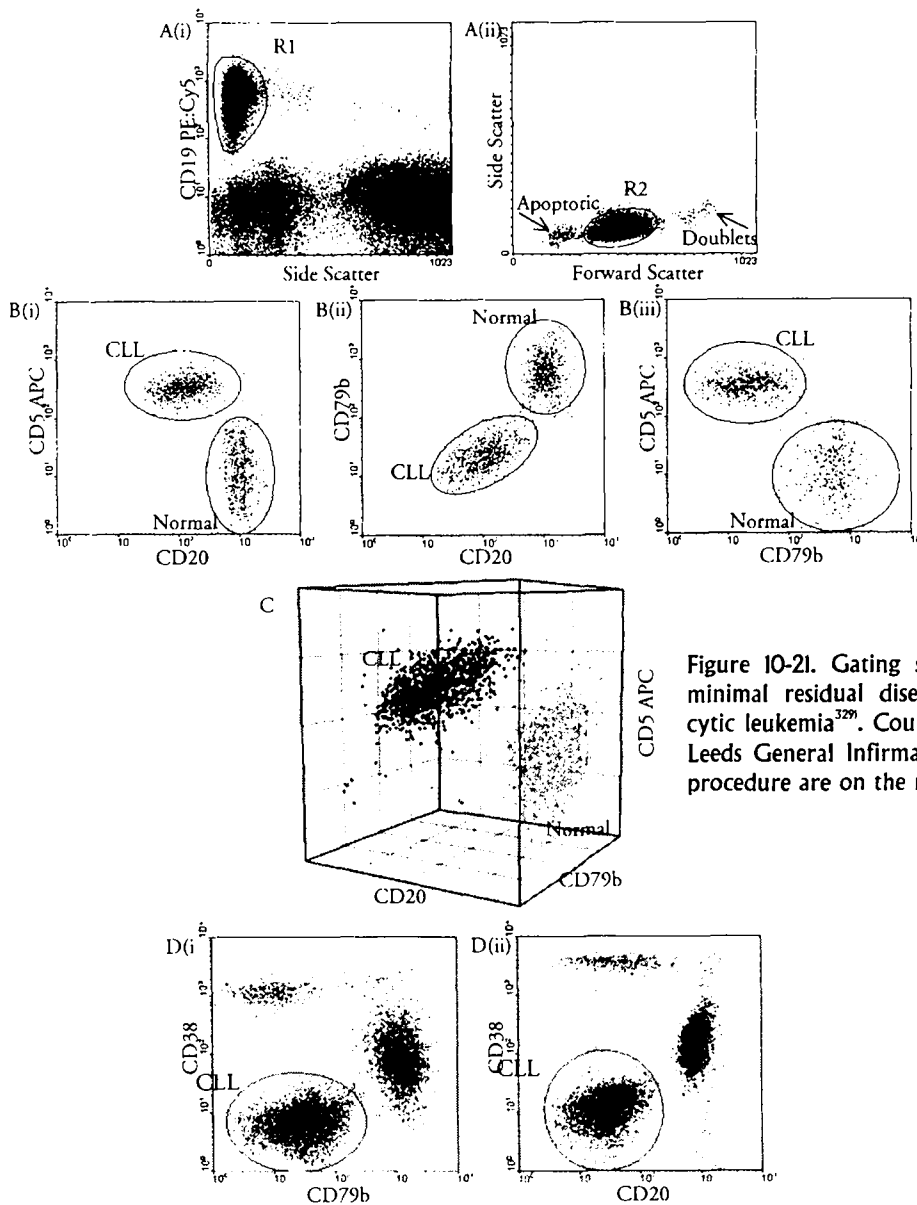

Figure 10-21. Gating scheme for detection of minimal residual disease in chronic lymphocytic leukemia<sup>329</sup>. Courtesy of Andy Rawstron, Leeds General Infirmary. Details of the gating procedure are on the next page.

several organizations to have made recommendations about procedure. The conclusions of a U.S.-Canadian Consensus Conference held in Bethesda (MS) in 1995 were published in *Cytometry (Communications in Clinical Cytometry)* in 1997<sup>327,5,80</sup>, and the most recent NCCLS Guideline was issued in 1998<sup>3281</sup>. In 2001, Braylan et al<sup>3282</sup> summarized the consensus of a meeting of international experts held at the ISAC 2000 Congress on the minimum number of antibodies required to evaluate hematologic and lymphoid neoplasias; figures ranged from as many as 8 antibodies for plasma cell disorders to as many as 24 for acute leukemias. The authors cautioned that reducing the number of antibodies could significantly compromise diagnostic accuracy, monitoring, and/or therapy.

A 2003 book by Nguyen, Diamond, and Braylan, *Flow Cytometry in Hematopathology. A Visual Approach to Data Analysis and Interpretation*<sup>3283</sup>, includes extensive examples of immunophenotyping in the text and on a CD-ROM. Phenotypic analysis of acute myeloid leukemia (AML) is discussed briefly on pp. 467-8; multiparameter phenotypes of

normal marrow and marrow from an AML patient are shown in color on the back cover.

### Detecting Minimal Residual Disease

In the leukemias and other neoplastic diseases for which effective therapy is available, it is useful to be able to detect **minimal residual disease** in blood or bone marrow specimens. While this is difficult in the absence of specific identifying characteristics, effective methodology has been described<sup>611,883,1010-1,1150,3284-7</sup>.

Patients judged to be in clinical remission by standard methods of marrow examination may have as many as 5% residual leukemic cells in the marrow. However, while patients with no residual disease by the more stringent flow cytometric criteria tend to stay in remission for long periods of time, patients in whom multiparameter flow cytometry reveals residual leukemic cells at levels exceeding more than 0.01% of marrow cells usually relapse early and die unless alternative therapy is available. In recent years, it has been possible to make the argument that the undeniably elegant

flow cytometric techniques used to detect minimal residual disease can also materially improve patient care in at least some hematologic malignancies<sup>3288-96</sup>.

Figure 10-21, on the preceding page, illustrates the gating scheme developed by Rawstron et al<sup>3291</sup> for detection of minimal residual disease in chronic lymphocytic leukemia<sup>3291</sup>. In the first step, [panel A(i)], region R1 defines a putative B lymphocyte population based on forward scatter and CD19 expression and lack of CD3 expression (the CD3 gating process is not shown); in panel A (ii), the scatter gate R2 is defined to exclude apoptotic cells and doublets. Panels B(i), B(ii), and B(iii) show expression of CD5, CD20, and CD79b on normal lymphocytes and CLL cells, as does the 3-dimensional display of panel C. In this particular case, CD79b expression on the leukemic cells is low; this varies from case to case, and that is the reason for the inclusion of measurements of both CD20 and CD79b in the procedure. The combination of antibodies to these antigens with antibodies to CD5 and CD38 enables detection of CLL cells with all known expression patterns, at levels of 1 in 100,000 nucleated cells. The patients followed by Rawstron et al were treated with CAMPATH-1 and/or autologous transplant; all patients with detectable residual disease (CLL cells more than 0.05% of total leukocytes) had progressively increasing levels of leukemic cells on follow-up.

This article was published in *Blood*; the figure in the journal illustrating the gating scheme was of substantially poorer quality than the one Andy Rawstron donated for this volume. The axis labels were almost illegible, and one or two were incorrect, because, once Andy had reduced the figure to the size specified by the journal, he couldn't read them any better than I could without a magnifying glass. So the published version of the figure was definitely an example of bad flow happening to a good journal. If you looked at the materials and methods section, the sources of antibodies were specified, but no mention was made of which labels were used for which antibodies; it turns out there are a few tricks involved there. There's a lot of flow cytometry in *Blood*, but it is not always as critical to articles as it was in this case, and, for a variety of reasons, the article really didn't contain enough information to enable a skilled flow cytometer user to implement the procedure described. Yet people do want to implement procedures like this, for the clinically relevant purpose of detecting minimal residual disease. Getting it right is essential if clinicians are to obtain the information they want about prognosis and therapy.

The cytometry community probably needs yet another set of guidelines to deal with this issue. Conceding that it is unlikely that journal articles will contain complete procedural details, we have to define ways of getting them. If the authors managed to get approval from a Human Experimentation Committee to do the research, they must have submitted a detailed protocol that should contain all the necessary information, so the obvious thing to do would be to contact the corresponding author and ask for a copy of the protocol, or an equivalent detailed description of the proce-

dure. As it happened, the e-mail address Andy Rawstron had given to *Blood* was inoperative due to various dor-complications, so I actually had to snail mail him to initiate a correspondence. He was an exceptionally good sport about the whole business, and I was pleased to say that the subsequent paper his group published in *Blood* about detecting neoplastic plasma cells in multiple myeloma patients<sup>3294</sup> included more legible figures and more procedural details.

But, getting back to my point, we all know that some antibodies work better than others, and that some labels work better than others, and that sample storage and preparation conditions may influence staining intensity, and we really need to have fairly rigid definitions of protocols to make sure everybody gets the right answers, especially when we need to quantify antigen expression, as may be necessary in analyzing cells from some leukemias<sup>3297</sup> and from patients with AIDS<sup>2689+92</sup>.

I should also point out that, since there are fewer than 10,000 new cases of acute myelocytic leukemia in the U.S. each year<sup>1752</sup>; flow cytometric phenotyping at remission is therefore not likely to be applicable to more than 7,000 patients annually, and will not be able to generate more than a few million dollars in annual revenue for all parties involved. Perhaps we need an Orphan Diagnostic Act, much like the existing Orphan Drug Act, to make technology such as this available in situations in which there are too few patients to enable manufacturers or providers to bring products to market profitably via normal channels.

Flow cytometry, and cytometry in general, are not likely to get bailed out in this way unless they provide better (and, one hopes, more cost-effective) ways of doing things than do competing technologies. PCR and flow compete in the area of detection of minimal residual disease; flow is reported to be at least as sensitive<sup>3298</sup>. In the near future, we may see some competition between phenotyping and DNA array technology<sup>3299</sup> for classification and prognosis, but it looks as if the genomic technology, like flow, is better for establishing prognosis than for selecting among treatment options.

### Biological Implications of Phenotyping Results

By now, marrow samples from thousands of patients with acute myelocytic leukemia, some with multiple leukemic clones, have been subjected to phenotypic analysis by multiparameter flow cytometry, and, as far as I know, no two clones are alike. This may tell us something about the biology of leukemias.

It is apparent that leukemia may result from various combinations of somatic mutations in hematopoietic cells. There may be dozens of possible mutations, yielding hundreds of genotypes, or perhaps even a few thousand genotypes. It doesn't seem all that likely, however, that there are many more genotypes than that.

We can then consider the likelihood of finding identical clones, given the number of genotypes we believe exist. This problem is similar to that posed in the mathematical puzzle that asks how many people must be in a room before there is

a better than even chance that two of them have the same birthday.

Neglecting leap years, there are 365 possible birthdays. If there are two people in the room, the probability is  $(364/365)$  that they do not have the same birthday; if there are three people, the probability is  $(364/365) \times (363/365)$ . For four people, the probability that no two share a birthday is  $(364/365) \times (363/365) \times (362/365)$ , and so on. When you get to 23 people, the probability that no two have the same birthday is less than  $1/2$ ; there is therefore a better than even chance that two of the 23 people have the same birthday.

If there were 365 leukemic genotypes, and if phenotype were completely determined by genotype, there would be a better than even chance that two identical phenotypes would have turned up by the time 23 marrow samples had been examined. However, many hundreds of samples have been examined, and no two phenotypes have been identical. This may simply mean that there are a lot more than 365 genotypes. If there were 1000 genotypes, I calculate that there would be even odds that two would be identical if 37 samples were examined. If no two phenotypes of over 300 are identical, either there are many thousand genotypes, or phenotype is not completely determined by genotype. The latter possibility is intriguing; it suggests that some host factor(s) might select for a particular leukemic phenotype.

This isn't all that farfetched. As I mentioned previously, a lot of reasonably smart people have been applying the methods of analytical cytology to normal and cancer cells for around forty years, and we still haven't found a consistent feature that differentiates all cancer cells from all normal cells. The whole definition of malignancy is, to some extent, an operational one; if it grows, spreads, and, when left untreated, eventually kills the patient, it's a cancer. I think it might be time to consider the medium in which cancer cells grow, i.e., the patient; maybe what we need to look for to define cancer in cytologic terms is a combination of characteristics of the tumor cells and characteristics of the host. This would certainly be compatible with what appears to be phenotypic selection.

The concept of **tumor stem cells** was recently revived following a report by Al-Hajj et al<sup>301</sup> that, among tumor cells isolated from nine human breast cancers, only those cells with a CD44+CD24- phenotype, which represented 1% or less of the population, readily induced tumors in immunocompromised mice. It made the newspapers.

### Digression: A Slight Case of Cancer

A number of people, taking different routes, have arrived at viewpoints similar to that just expressed. I got there as a very interested spectator and patient, after undergoing a partial gastrectomy and radiation therapy for a mucosal ("MALT") lymphoma of the stomach that was diagnosed in 1991.

As an oncologist, I couldn't have asked for a better variety of cancer. Most gastric lymphomas are slow-growing,

and prospects for long-term survival following treatment by surgery and irradiation are excellent<sup>1772</sup>. For many years, what are now known to be gastric lymphomas were classified as "pseudolymphoma," reflecting the fact that they looked like lymphomas, but apparently did not spread to lymph nodes or elsewhere, and the observation that patients might survive for ten years or more without any treatment other than antacids and ulcer drugs, which relieved the symptoms of pain and bleeding.

Modern thinking on gastric lymphomas is largely based on the work of Peter Isaacson, of University College and Middlesex School of Medicine, London, and his colleagues. Isaacson was largely responsible for the definition of the concept of **MALT lymphomas** (i.e., lymphomas of **Mucosal Associated Lymphoid Tissue**)<sup>1773</sup>. Although gastric MALT lymphomas are among the most common tumors of this type, mucosal associated lymphoid tissue is not present in the normal stomach. MALT lymphomas of other sites in which lymphoid tissue is not normally found, e.g., the salivary gland and thyroid, arise following the acquisition of lymphoid tissue in these organs as a result of autoimmune disease (Sjogren's syndrome and Hashimoto's thyroiditis, respectively); in the stomach, lymphoid follicles develop in association with chronic gastritis.

The predominant cell in what were called pseudolymphomas is a B cell resembling the centrocytes seen in the lymphoid follicles normally present in the intestinal submucosa. It is phenotypically CD21<sup>+</sup>CD35<sup>+</sup>CD5<sup>+</sup>CD10<sup>-</sup>. Isaacson based his reclassification of pseudolymphomas as lymphomas in part on monoclonality, which is demonstrable by light chain staining and heavy chain gene rearrangement; there is no rearrangement of either *bcl-1*, *bcl-2*, or *c-myc*<sup>1774</sup>. Other evidence for the neoplastic nature of the cell comes from cytogenetics; rearrangements of chromosome 1p, trisomy 3, and trisomy 7 have been found<sup>1775</sup>.

Intensive pathologic examination of gastrectomy specimens from a small number of patients showed that in all cases, small foci of lymphoma distinct from the original lesion were scattered throughout the specimen<sup>1776</sup>; the apparent multifocal nature of the tumor could explain the development of local relapse after a long disease-free interval, which is typical of the relatively infrequent recurrences that do occur.

It was thought that the propensity of the tumor to remain localized, rather than spreading to lymph nodes, marrow, etc., was due to the centrocyte-like nature of the neoplastic cells; normal centrocytes did not appear to recirculate. However, by using anti-idiotypic antibodies, Isaacson's group demonstrated scattered MALT lymphoma cells in anatomically and otherwise histopathologically normal lymph nodes and spleen removed during surgery for gastric lesions.

The gastritis leading to the development of lymphoid tissue in the stomach occurs as a consequence of infection by *Helicobacter pylori*; this organism, which is also associated with peptic ulcer disease and gastric carcinoma, was identi-

fied in biopsy or surgical specimens from 101 of 110 patients (92%) with gastric MALT lymphomas<sup>177</sup>.

Isaacson hypothesized that gastric MALT lymphomas result from neoplastic transformation of cells involved in a normal immune response. In one test of this hypothesis, he placed cells from several gastric MALT lymphomas in culture with several strains of *H. pylori*, using other bacteria and phorbol ester as control stimuli. Phorbol ester induced proliferation of cells from all specimens; the neoplastic B cells proliferated otherwise only in the presence of both the specific strain of *H. pylori* found in the patient and T cells also taken from the tumor<sup>177,8</sup>. This pattern of antigen- and T cell-dependent proliferation *in vitro* is consistent with the observation of microscopic foci of tumor, but not of larger lesions, in areas where antigen, in this case *H. pylori*, is absent. Interestingly enough, the immunoglobulins produced by the neoplastic B cells appear to react with autoantigens, rather than with *H. pylori*<sup>177,9,80</sup>.

Working with Isaacson's group, Claudio Doglioni had documented a high incidence of both gastric MALT lymphoma and *H. pylori* infection in northeastern Italy<sup>178</sup>. They conducted a brief clinical trial there in which six patients with gastric MALT lymphoma demonstrated by endoscopic biopsy were treated with bismuth salts (i.e., Pepto-Bismol or its equivalent), metronidazole, and amoxicillin for two weeks to eradicate *H. pylori*. Follow-up biopsies were done 4 to 10 months later; in five of six patients, the lymphoma had disappeared, i.e., PCR failed to demonstrate residual disease in the stomach<sup>178,2</sup>.

I heard Isaacson speak in Boston in May, 1993, before his clinical study was published, and became a convert; I took the therapy for *H. pylori* (\$30 worth of pills), just to be on the safe side. Since the lecture was delivered to an audience of pathologists, I prepared a summary, with references and circulated it to the gastroenterologist, oncologists, radiotherapist, and surgeon who had treated me. The results were interesting. I had asked my gastroenterologist about *Helicobacter* when I first had ulcerlike symptoms, before my diagnosis of lymphoma was established; at the time, he, like many others in Boston, was skeptical about the role of the organism in ulcer disease or anything else. After I told him about Isaacson's work, he had the pathologists pull out my specimen and look for *H. pylori*; they found the bacteria. I should have placed a bet.

There are big picture conclusions and little picture conclusions to be drawn from all this; let's look at the big picture first. I agree with Isaacson that MALT lymphomas probably aren't the only neoplasms in which the host environment provides some stimulus for tumor growth, and expect that this new paradigm may usefully be extended to other, more common cancers. Based on everything known about gastric MALT lymphomas, I am unlikely to have even a local recurrence of mine. However, there's another paradigm shift here. Where the prevailing wisdom was that the low rates of recurrence and spread were due to the localized, noncirculating nature of the neoplastic cells, the present

picture, based on the anti-idiotypic antibody studies, is that the cells do circulate. I got radiation therapy to the region of what's left of my stomach, which might have killed tumor cells remaining around there, but which almost certainly wouldn't have killed tumor cells in distant lymph nodes or my bone marrow. The likelihood is that those cells won't bother me. This goes completely against one of the central dogmas of cancer treatment, which is that curing the patient requires the eradication of every last cancer cell.

Taking *H. pylori* and the T cells responding to it out of the picture to eliminate the growth factors needed by the neoplastic B cells in a gastric MALT lymphoma isn't all that different from taking estrogen away from breast cancer cells which need it to grow. It also isn't that uncommon to find microscopic foci of breast cancer cells at autopsy in patients who were supposedly cured and died years later of something else. The fact is that most cancer cells are a hell of a lot harder to grow *in vitro* than they are to grow in their hosts; we might want to pay a little more attention to the role of host factors in looking at new modalities of treatment.

As for the smaller picture, being a dedicated analytical cytologist, I made sure that my cells got worked up; they were reported to be monoclonal for lambda light chain (MALT lymphomas are not classified as chocolate and vanilla), and, by flow cytometry, they were DNA diploid. However, since there is a history of lymphoma on both sides of my family, I thought it might be appropriate to look into the cytogenetics; the cells were found to have two extra chromosomes. If I tried hard, I could probably detect remaining cells in my marrow using DAPI and anti-lambda antibodies; for the time being, I prefer to let David Hedley remain as the only person I know who takes sternal marrow samples from himself.

From the point of view of a writer or a reader of a book on flow cytometry, one of the most sobering aspects of this whole story relates to Isaacson's methodology. There was no flow cytometry involved; no image analysis, either. All of the anti-idiotypic and other antibody and gene probe work was done using enzyme-linked systems and transmitted light microscopy. If you go to the same meetings I do, you're probably used to seeing chromosome probes under fluorescence microscopes; in Isaacson's slides, they showed up as blue or brown dots on Giemsa-stained chromosomes. And, try as I might, I couldn't really think of any way in which flow or image cytometry would have enabled the work to be done better, or faster, or cheaper (and, almost nine years later, I still can't).

### Analysis of Sperm

The use of flow cytometry and cell sorting for separation of X- and Y-sperm has been discussed on pp. 26, 282, 310-1, and 452-3.

**Assessment of the quality of animal and human sperm** by flow cytometry has been looked at in evaluation of infertility in animals and humans. Evenson, Darzynkiewicz and Melamed<sup>31</sup> approached this issue by correlating micro-

scopic observations of sperm mobility with **dye exclusion** and **mitochondrial membrane potential** measurements, but found **chromatin structure**, as measured using acid denaturation and acridine orange, to be the most reliable indicator of sperm quality<sup>941-3</sup>. The **Sperm Chromatin Structure Assay (SCSA)** correlates well with alternate tests of sperm quality in bulls<sup>944-5,1982</sup>. Evenson et al<sup>3302</sup> compared SCSA measurements made on various arc lamp and laser source flow cytometers and found that, while there were differences in the appearance of displayed data from different instruments, all produced equivalent results. Evenson and Jost<sup>3303</sup> reviewed the SCSA in 2002.

Auger et al<sup>1983</sup> correlated mitochondrial membrane potential of sperm, as measured using rhodamine 123, with motility, and were able to use R123 fluorescence to sort highly motile sperm<sup>1984</sup>; more recently, Marchetti et al<sup>3304</sup> concluded that "Analysis of mitochondrial membrane potential is the most sensitive test by which to determine sperm quality." However, the sensitivity of membrane potential measurements does not appear to be related to their capacity to indicate apoptosis. Using annexin V staining, Ricci et al<sup>3305</sup> found no significant differences in the percentages of apoptotic sperm or of leukocytes in semen classified as normal and abnormal by WHO criteria.

Ericsson et al<sup>1985</sup> found carboxymethylfluorescein diacetate and hydroethidine useful in assessing viability of cryopreserved sperm, although they did not observe correlations between flow cytometric quality indicators and motility<sup>1986</sup>. The same group evaluated the toxicity of dyes to sperm cells; Hoechst 33342, hydroethidine, and a tracking dye decreased oxygen consumption, although R123 did not<sup>1987</sup>.

Yeung et al<sup>3306</sup> studied 488 nm forward and side scatter and Coulter volume of sperm, and found that infertile sperm from knockout mice were larger than fertile sperm from heterozygous mice, suggesting that volume regulation may be critical for sperm function.

Haas and Cunningham<sup>946</sup> investigated another aspect of infertility using flow cytometry; they were able to detect and quantify **antibodies bound to sperm**. Haas and his colleagues<sup>1988-92,1995</sup> and others<sup>1993-4,1996-8</sup> have continued to use flow cytometry for this purpose; in comparative studies, it demonstrates advantages over alternative techniques<sup>1992,1998</sup>.

The progress of the **acrosomal reaction** essential for sperm to become capable of fertilization can be monitored using fluorescent antibodies and lectins<sup>1424,999-2005</sup>. Harrison, Mairer, and Miller<sup>1734</sup>, studying the effects of buffers used with sperm for *in vitro* fertilization, observed that bicarbonate in the buffer, which induced the calcium influx necessary to begin the acrosome reaction, also appeared to increase the number of cells with damaged membranes.

**DNA content analysis of testicular aspirates and biopsies**<sup>2006-13</sup> has proven useful in the evaluation of infertility, including that induced by cancer treatments; sperm are readily detected by their haploid DNA content, allowing their relative numbers to be estimated. Regarding DNA analysis in biopsies of undescended testes, in which cancer is likely to

develop, Clausen et al<sup>2013</sup> note that DNA aneuploidy can occur in an undescended testis without any evidence of malignancy, and suggest it may indicate a preneoplastic state.

Commercial flow cytometers adapted for sperm counting are now available. BD Biosciences has produced a system of stains (SYBR-14 or propidium), diluent, and counting beads allowing the FACSCount (p. 418) to be used for sperm counting<sup>3307</sup>; Tsuji et al<sup>3308</sup> have reported on another device, the S-FCM.

**Laser scanning cytometry** and FISH were found useful by Baumgartner et al<sup>3309</sup> for detection of aneuploid sperm.

### Isolating Fetal Cells from the Maternal Circulation for Prenatal Diagnosis

During pregnancy, both trophoblastic and blood cells from the fetus may enter the maternal circulation, in which they represent fewer than 1 of every 10<sup>5</sup> nucleated cells. The development of reliable methods for isolation of such fetal cells would provide a simple, low-risk alternative to amniocentesis and chorionic villus sampling for acquisition of cell samples for prenatal genetic diagnosis using *in situ* hybridization, PCR, and other molecular biologic methods. Bruch et al<sup>1812</sup> sorted trophoblast-like cells from maternal blood using three monoclonal antibodies against trophoblast, and, via PCR, found Y-specific sequences in two of three samples from mothers carrying male fetuses, although most of the sorted cells appeared to be maternal leukocytes. A higher purity of trophoblastic cells was obtained by combining immunomagnetic removal of maternal lymphocytes and sorting using antitrophoblast antibodies; fluorescence *in situ* hybridization with a Y-centromeric probe allowed detection of 47,XYX fetal cells<sup>1813</sup>.

An alternative approach is based on isolation of fetal nucleated erythrocytes, which appear in the maternal circulation early in gestation. Bianchi et al<sup>1814</sup>, using multiparameter sorting, isolated cells positive for the transferrin receptor (CD71) and negative for the CD3 and CD14 leukocyte antigens; Y chromosomal DNA sequences were detected in samples obtained at 11 and 12 weeks' gestation, and absent in subsequent samples at 16, 19, and 20 weeks, from women who delivered males, while Y DNA was not detected in two women who delivered females.

Price et al<sup>1815</sup> sorted fetal nucleated erythrocytes on the basis of a combination of forward and right angle scatter and the presence of CD71 (transferrin receptor) and glycophorin A on the cell surface. From such flow-sorted samples, Wachtel et al<sup>1816</sup> correctly identified fetal sex in 17/18 (94%) pregnancies of 10-21 weeks gestation. Their group also reported diagnosis of trisomy-21 in fetal cells from maternal blood<sup>1817</sup>, as did Bianchi et al<sup>1818</sup>.

Although specificity of fetal cell detection has been improved by use intracellular staining with antibodies to the gamma globin chain of hemoglobin F<sup>3310-2</sup>, recent clinical studies have combined immunomagnetic separation, with negative selection for CD45+ cells<sup>3310</sup> and positive selection for cells containing gamma globin<sup>3312</sup>, with flow sorting. The

NIFTY I multicenter trial<sup>3313</sup> were better using magnetic cell separation conducted by the National Institute of Child Health and Human Development found that target cell recovery and fetal cell detection were better using magnetic separation alone than with flow sorting with or without magnetic separation. All separation methods yield both fetal and maternal cells; discrimination of the two populations, which is essential for interpretation of FISH data used for prenatal diagnosis of trisomies, is most effectively accomplished using morphologic as well as biochemical criteria<sup>3314</sup>, suggesting that the utility of flow cytometry in this field may be limited.

### The March of Time: Circadian Rhythms, Aging, and Atherosclerosis

Periodic phenomena can only be effectively studied by methods that consume relatively little time compared to the period involved. Thus, it was really not possible to learn much about **circadian periodicity** of cell kinetics as long as kinetic studies required autoradiographic analysis with exposure times of weeks. Since DNA flow cytometry can be accomplished in minutes, it has been feasible to use the technique to discover circadian variations in cell proliferative activity in tissues<sup>2028-36</sup> and tumors<sup>957,2027</sup>, and to analyze resulting circadian variations in drug effects<sup>958</sup>, which may eventually be exploitable for scheduling kinetic-based therapy<sup>959,2032</sup>.

Circadian fluctuations in counts of various blood cell types have been reported<sup>2037</sup>; this may have unwanted effects in following progression in such diseases as HIV infection<sup>2038-9</sup>. Circadian rhythms also affect the growth and metabolism of single-celled organisms such as the dinoflagellate *Gonyaulax*<sup>2040-1,2049</sup>.

Changes at the cellular level related to **aging** can be investigated either by comparing cellular samples from young and old individuals or by examination of cells such as fibroblasts subjected to *in vitro* aging. Considering the popular hypothesis that aging is associated with impaired defenses against free radical reactions, Poot et al<sup>960</sup> examined glutathione recovery rates following oxidative stress in *in vitro* aged fibroblasts and in fibroblasts from patients with several metabolic diseases and found no impairment in comparison with normal cells. Martinez et al<sup>961</sup> quantified rhodamine 123 mitochondrial fluorescence in young (6 population doublings) and old (41 population doublings) fibroblasts, and found increased fluorescence in the older population. Cristofalo<sup>2042</sup> found the S-phase fraction and cell density to be independent biomarkers of aging in cell cultures. Differences in lymphocyte responses with age have been reported (e.g., references 1690 and 1692).

Aging has also been associated with reported increases in **DNA polyploidy** in several tissue types, including heart muscle and vascular smooth muscle<sup>962,2043-4</sup>. Similar increases in polyploidy in vascular smooth muscle occur following injury of the type used to induce experimental **atherosclerosis**. A methodological problem in this area of research lies in the necessity to discriminate tetraploid cells from doublets

due to aggregation or proximity of diploid cells in the flow cytometer; Vliegen<sup>963</sup> et al have developed a mathematical procedure to correct for background and clumping. Independent confirmation that the observed polyploidy is not entirely artifactual was obtained when polyploid cell lines were isolated and cultured from rat aortas by Goldberg et al<sup>964</sup>. Black et al<sup>2045</sup> established that vascular smooth muscle polyploidy parallels inhibition, reversal, and redevelopment of **hypertension** in an experimental model, the spontaneously hypertensive rat. On another front, Stemme, Holm, and Hansson<sup>2046</sup> reported that T lymphocytes, which are found in abundance in atherosclerotic plaques, are memory cells (CD45RO<sup>+</sup>); they also express the very late activation antigen VLA-1.

Although I have not done an extensive search of literature in this area since the previous edition, I suspect that the cytometric analysis of **platelet activation in atherosclerotic disease** (see p. 487) represents a significant contribution.

### Clinical Application: Urine Analysis

International Remote Imaging Systems' "Yellow IRIS<sup>TM</sup>" workstation<sup>1019</sup> was the first of a series of flow cytometers with imaging capability intended for analysis of urine specimens. Image data can be reviewed by an operator. The current instruments (p. 431) are the **Model 500 Urine/Fluids Workstation** and the **939UDx<sup>TM</sup> Urine Pathology System**; the former is manually fed, while the latter is completely automated. Both provide chemical as well as cytometric analyses of urine.

**Sysmex** manufactures the **UF-100<sup>3315-7</sup>** and **UF-50** urine analyzers; both combine fluorescence, light scattering, and impedance measurements to classify and count formed elements in blood. The numbers denote the number of samples the instruments can process per hour.

### The Animal Kingdom

#### Lions and Pumas and Clams, Oh, My!

Flow cytometry has been and is being applied to a lot of species these days. Since, when the moon is full, I grow black and white fur and eat bamboo shoots, preferably with hoisin sauce, I decided to try to get flow cytometric data from giant panda cells to put into the Third Edition. I called Stephen O'Brien, of the National Cancer Institute, who used molecular genetic techniques to determine that the giant panda is a bear<sup>1964</sup>, and asked whether he had ever done analyses of panda cells. No luck there, but, as it turned out, Eric Brown, a predoctoral student in his lab, sent me the contour plots of T cell subset analysis in a lion (*Panthera leo*) and a puma (or cougar, or mountain lion) (*Felis concolor*) shown in Figure 10-2. The antibodies used are the same ones used for T cell subset analysis in domestic cats, and the analyses are done for the same reason; the big cats can carry the same feline leukemia retrovirus as their smaller relatives. Bull et al<sup>3318</sup> recently studied polymorphic expression in the lion CD8alpha chain.

Dr. O'Brien's collaborators on the panda work, at the National Zoo, put me in touch with Dr. Marcia Etheridge, of the Department of Comparative Medicine at Johns Hopkins University School of Medicine, who has analyzed blood or its equivalent from a number of animal species on an Abbott Cell-Dyn 3500 hematology analyzer; Figure 10-23 shows clusters of clam cells on 2-dimensional histograms using essentially the same parameters as are shown in Figure 10-16 (p. 483), which depicts human blood.

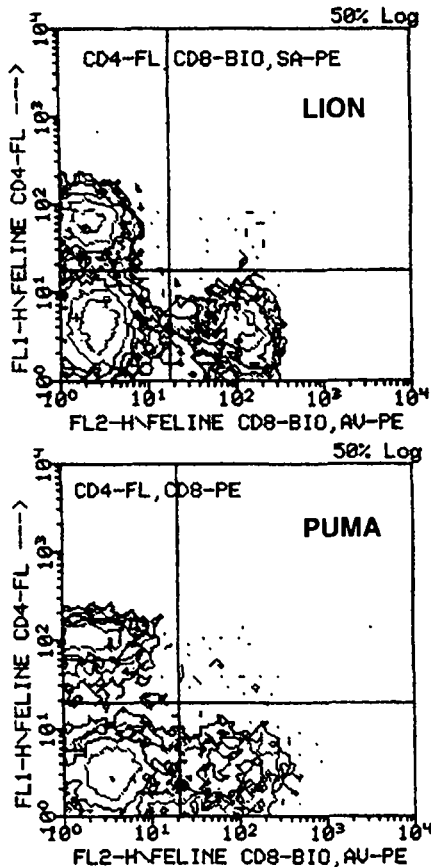

Figure 10-22. T cell subset analysis in lion (top) and puma (bottom) peripheral lymphocytes. The figure was provided by Eric Brown and Stephen O'Brien (National Cancer Institute).

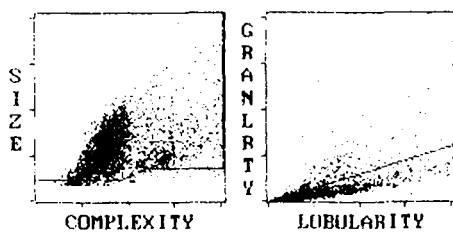

Figure 10-23. Analysis of clam cells in a Cell-Dyn 3500 hematology analyzer (see Figure 10-16, p. 483, for a comparison with human blood). The Figure was provided by Marcia Etheridge (Johns Hopkins University).

The phagocytic properties of clam hemocytes<sup>3319</sup> are relevant to pathology<sup>3320</sup> and toxicology<sup>3321</sup>, and have been studied in those contexts using flow cytometry.

Flow cytometry can get the lion, or at least its cells, to lie down with the lamb, as well as the clam. Some interesting mathematical and statistical methods for extracting protocom information from patterns of antibody binding to cell surface proteins<sup>2491,3322-3</sup> have emerged from my colleague Steve Mentzer's interest in the immunobiology of the sheep<sup>3324</sup>, a favorite lab animal for thoracic and cardiac surgeons.

Blood from most mammals is closer to the human/lion/lamb model than the clam model. Wang et al<sup>1965</sup> showed that forward and right angle scatter could be used to perform three part differential leukocyte counts on porcine blood; Jain, Paape and Miller<sup>1966</sup> combined two-angle scatter and acridine orange fluorescence measurements for a differential count of bovine leukocytes which they reported discriminated eosinophils from other granulocytes.

Blottner et al<sup>3325-6</sup> have used flow cytometry of DNA content and vimentin expression to study spermatogenesis and seasonal variations in spermatogenesis in cattle, roe deer, brown hares, and mink. It's not clear whether they've gotten into a rut or just have a lot of seed money.

Starck and Beese<sup>3330-1</sup> combined flow cytometry with light and electron microscopy study cytological mechanisms involved in the rapid size changes of the small intestine and liver that are associated with feeding in snakes, using pythons and garter snakes as examples. They found that cell proliferation is not involved in the upregulation of organ size, but increases during downregulation, as cells worn out during the digestive process are replaced.

When I put out a call on the Purdue Cytometry Mailing List for flow cytometric data from giant pandas for this edition of the book, I got helpful e-mails from a lot of people, but the bottom line was that nobody seemed to have done flow cytometry on one. I found out that there are monoclonal antibodies that react with cell surface antigens in other bears and would therefore be potentially useful in studies of the immunological problems said to occur in pandas. E-mail me ([hms@shapiroolab.com](mailto:hms@shapiroolab.com)) if you're interested.

### Fish Story; FISH Story

I am informed that breeding sterile, triploid hybrids is a technique common in fisheries for preventing fish (vertebrates) and shellfish (invertebrates) from reproducing. While this sounds counterproductive, it isn't (look at beef); oysters, for example, survive (and stay marketable) longer if they don't bother to reproduce. Flow cytometry is, of course, a pretty good technique for determining whether you've achieved triploidy or not, and has been used for the purpose<sup>251-2</sup>.

Genome size of diploid organisms, fish included, as indicated by DNA content, is useful for studies of classification and evolution. Ciudad et al measured DNA content of goldfish, tench, and zebrafish<sup>3332</sup>; Brainerd et al analyzed DNA

content of different groups of pufferfish<sup>3333</sup>, and suggested that the smooth pufferfish, which have the smallest genome sizes (0.7-1.0 pg diploid) measured to date in vertebrates, derive from ancestors with somewhat larger genomes.

While nobody seems to have done 11-color flow cytometry on fish cells, the ranges of probes used, parameters measured, and species subjected to cytometric analysis continue to expand. For example, Wong and Chan<sup>3334</sup> used rhodamine 123 staining to identify, and determine effects of cortisol on, chloride cells in the gills of Japanese eels.

The immune system supposedly evolved in fish; there is a journal called *Fish and Shellfish Immunology* in which you can expect to find a lot of flow cytometry, monoclonal antibodies and all, just as you would in almost any other immunology journal. In it, Inoue et al<sup>3335</sup> reported that staining with DiOC<sub>6</sub>(3) and measurement of forward and side scatter and fluorescence allowed resolution of five separate cell populations in fish blood, i.e., erythrocytes, thrombocytes mixed with lymphocytes, monocytes, neutrophils, and basophils. The same trick works with bird (quail) blood<sup>3336</sup>.

Mayer et al<sup>3337</sup> isolated lymphocyte-like cells from sea lamprey intestine using forward and side scatter, and prepared a cDNA library with which they were able to determine that the lamprey cells contained many genes homologous to those found in human lymphocytes. Sequences with similarity to MHC, T cell receptor, or Ig genes were notable by their absence, suggesting to the authors that "the evolution of lymphocytes in the lamprey has reached a stage poised for the emergence of adaptive immunity."

The subject of genetic homologies easily gets us from fish to FISH, and the technique of "Zoo-FISH," or comparative chromosome painting, in which probes derived from flow sorted human chromosomes are used to detect homology with chromosomes of other mammalian species<sup>3338-43</sup>. Cat and human karyotypes are reported to resemble the putative ancestral mammalian karyotype<sup>3339</sup>, while a comparison of human and harbor seal (*Phoca vitulina*) chromosomes shows resemblance to the putative ancestral carnivore<sup>3341</sup>. I guess you need to do Zoo-FISH on various seal species to find the karyotype of the average ancestral seal, or mean mother *Phoca*.

### Flow Cytometry: For the Birds?

De Vita et al<sup>3314</sup> found DNA content potentially useful in sex identification in birds of prey, many of which are sexually monomorphic, which means it's hard to tell males from females by inspection. If you're trying to breed endangered falcons, and your pair contains two birds of the same sex, there won't be any falcon around. Sorry, I couldn't resist. It's a nice paper.

Having found flow cytometry applied to hawks, I thought I'd see if it had been applied to doves, as well. The closest I got was a paper by Itoh et al<sup>3332</sup> on binding of pigeon cytochrome C peptides to I-ab and the T cell receptor. There appear to be structural similarities between the pigeon

peptides and MHC proteins, but probably just by coincidence.

### Big Stuff, Vegetable, Animal or Mineral

Since a good deal of the hardware technology of flow cytometry and sorting was developed by people interested in looking at lymphocytes and other small cells, most existing instruments require some modification to be usable for analysis and/or sorting of larger objects<sup>671</sup>, be they **plant cells or protoplasts**<sup>673</sup>, **tumor cell spheroids**<sup>672</sup>, **pancreatic islets**<sup>1227</sup>, or **megakaryocytes**. Large cell sorting was discussed in Chapter 6 (pp. 264-6). Both droplet sorters with large (> 200 μm) orifices and fluidic switching sorters have been used to sort a variety of appropriately sized specimens.

If there is a *Guinness Book of Records* in this area, the entry for largest objects subjected to flow cytometry might go to brine shrimp; in 1965, Linus Pauling and his colleagues counted these organisms by extinction measurements in a flow system<sup>585</sup> in conjunction with studies on the mechanism of anesthesia. Optical plankton analyzers<sup>1167-8</sup> may also be able to handle objects in this range. However, I also remember reading something years back about an optically activated fluidic potato sorter... .

Moving back to the animal world, I already mentioned (p. 265) that a modified Partec fluidic sorter had been used to sort pancreatic islets<sup>1227</sup>. A stain combining the dye neutral red and the chelating agent dithizone gave an 83% yield and 80% purity<sup>2020</sup>. On the other hand, a paper by Halban et al<sup>2021</sup>, who used a conventional sorter to purify individual cell types from islets, and then mixed them in culture, reported that the cells will reaggregate to form structures resembling islets, so the cell transplant folks may not need to sort whole islets after all.

Large particles tend to settle faster than smaller ones, which can lead to problems during long analysis and sorting runs. Freyer, Fillak and Jett<sup>2050</sup>, working with multicellular spheroids, found that adding 0.1% **xanthan gum** to suspensions greatly increased static viscosity, preventing settling of the particles in the sample tube. The gum does not increase viscosity in flow, and therefore does not interfere with sorter operation.

### Flow Cytometry of Plant Cells and Chromosomes

A 1986 review by Brown et al<sup>947</sup> on flow cytometry in plant biology cited 44 references, remarking that the literature more than doubled in the two years since a previous review had appeared. There are now enough references to justify a book on applications of flow cytometry to plants, but, as far as I know, nobody has written one. However, Brown and Coba de la Pena<sup>3344</sup> have contributed a chapter on cytometry to a recent book on plant cell biology. Galbraith<sup>3345</sup> and Blackhall<sup>3346</sup> have reviewed flow cytometry and sorting of plant cells, and Lucretti and Doležel<sup>506</sup> and Doležel et al<sup>3347-8</sup> have discussed methodology for flow cytometric analysis of plant chromosomes.

In general, people who do flow cytometry on materials from plants are measuring the same things the rest of us are used to measuring in animal cells, and facing many of the same problems.

Pollen is the most readily accessible single cell sample available from plants; however, since the objective in flow cytometry of plant materials is typically the study of some aspect of differentiated function, the samples commonly analyzed are cell suspensions or protoplasts<sup>948,2016-8,3345-6,3349</sup>. Chromosomes<sup>949,3061-2,3065,3067,3071</sup> and plant subcellular organelles such as chloroplasts and mitochondria have also been subjected to flow cytometric analysis.

Major areas of application of flow cytometry to plants include **measurement of DNA content** for taxonomic and other purposes<sup>3350</sup> and **analysis and sorting of plant chromosomes**. Figures 10-24, 10-25, and 10-26, illustrating these applications, were provided by Dr. Jaroslav Doležel, of the Laboratory of Molecular Cytogenetics and Cytometry, Institute of Experimental Botany, Olomouc, Czech Republic. A bibliography of the many publications of Dr. Doležel's group is available online at (<http://www.ueb.cas.cz/olomouc1>).

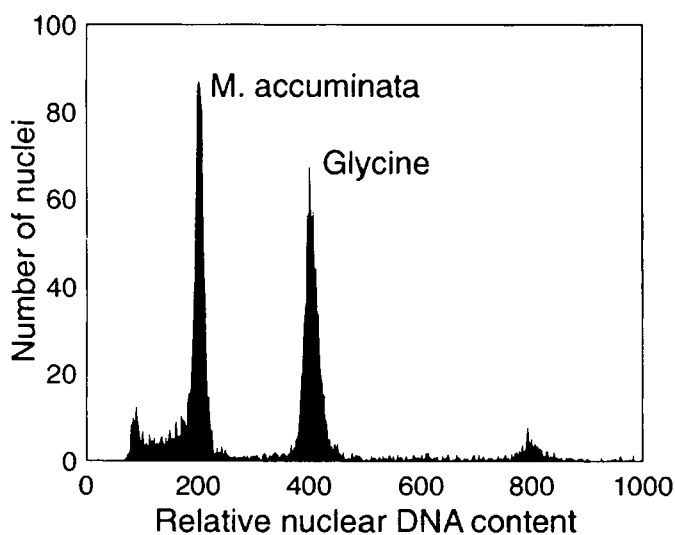

Figure 10-24. Determination of nuclear genome size in diploid banana (*Musa acuminata* "Calcutta 4"). Nuclei isolated from soybean (*Glycine max*, 2C = 2.50 pg DNA) were used as an internal reference standard. The small peak at channel 800 represents soybean nuclei in G<sub>2</sub> phase. Nuclear DNA content of *Musa* was estimated following the formula:  $Musa\ 2C\ DNA\ content = (Musa\ G_1\ peak\ mean \div soybean\ G_1\ peak\ mean) \times 2.50\ [pg\ DNA]$  and was found to be equal to 1.23 pg DNA. Courtesy of Jaroslav Doležel.

#### Measurement of Plant Cell DNA Content

Figure 10-24 illustrates determination of the 2C DNA content of a strain of bananas. A reference standard of known DNA content, soybean in this case, is used. Johnston

et al<sup>3351</sup> recommended five species with a broad range of 2C DNA contents as standards: *Sorghum bicolor* cv. Pioneer 8695 (2C = 1.74 pg), *Pisum sativum* (pea) cv. Minerva Maple (2C = 9.56 pg), *Hordeum vulgare* (barley) cv. Sultan (2C = 11.12 pg), *Vicia faba* (broad bean) (2C = 26.66 pg), and *Allium cepa* (onion) cv. Ailsa Craig (2C = 33.55 pg). The reference standard should be one with 2C and 4C nuclear DNA content peaks close to, but not overlapping, the 2C and 4C peaks of the target species. Propidium iodide, which has no bias for A-T- or G-C-rich sequences within genomes, is recommended as the fluorochrome of choice for determination of plant DNA content; DAPI (A-T preference) should be used only if the estimated DNA value is corroborated using a second stain.

The Royal Botanic Gardens, Kew, UK, maintains a database of DNA content values; they are "C-values," i.e., values of DNA content in a haploid gamete nucleus, rather than the "2C-values" that would be obtained from somatic cell nuclei as shown in Figure 10-24. The URL is (<http://www.rbkew.org.uk/cval/homepage.html>). The Plant DNA C-values Database contained data for 3,927 different Embryophyte plant species as of January, 2003; it combines data from Angiosperm, Pteridophyte, and Gymnosperm databases. If you would like to stop and smell the roses at this point (2C = 0.78-1.33 pg), see Yokoya et al<sup>3352</sup>.

Vinogradov<sup>3353,3354</sup> suggested that plants with larger genome sizes should have higher G-C percentages; however, studies of a number of plant species<sup>3354-5</sup> have not found a significant correlation.

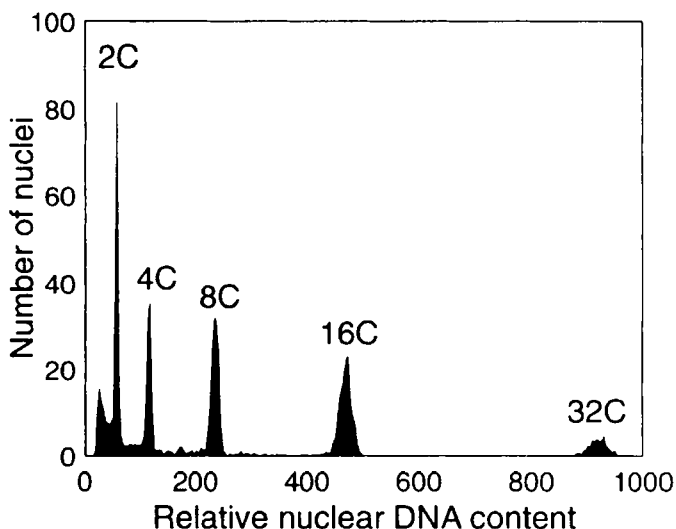

Figure 10-25. Histogram of relative nuclear DNA content of nuclei isolated from parenchymatic tissue of a young cactus plant (*Mammillaria san-angelensis*). Note the presence of peaks representing endopolyploid nuclei with DNA content reaching 32C. Courtesy of Jaroslav Doležel.

As Figure 10-25 shows, DNA content measurement may reveal cells with endopolyploid nuclei in plant tissue; this is a good reason to keep C-values in the database. DNA content

measurement can also be used to determine sex in dioecious plants; however, since the difference in DNA content between male and female plants is typically only a few percent, it is necessary to use a high-resolution flow cytometer. Doležel and Göhde<sup>3356</sup> were able to resolve 3.7% differences in DNA content between male and female *Melandrium album* and *M. rubrum* using a Partec arc source flow cytometer and DAPI staining; they obtained G<sub>0</sub>/G<sub>1</sub> peak CVs of 0.53-0.70 % using a modification<sup>3357</sup> of the nuclear isolation technique originally published by Galbraith et al<sup>3358</sup> and an analysis rate of 20-50 nuclei/s. Pfosser et al<sup>3359</sup>, using high-resolution flow cytometry, were able to detect aneuploidy resulting in differences in DNA content as small as 1.84 percent.

Houssa et al<sup>2016</sup> described a high-yield isolation procedure permitting flow cytometric analyses of DNA to be done using micrograms of shoot meristematic tissue.

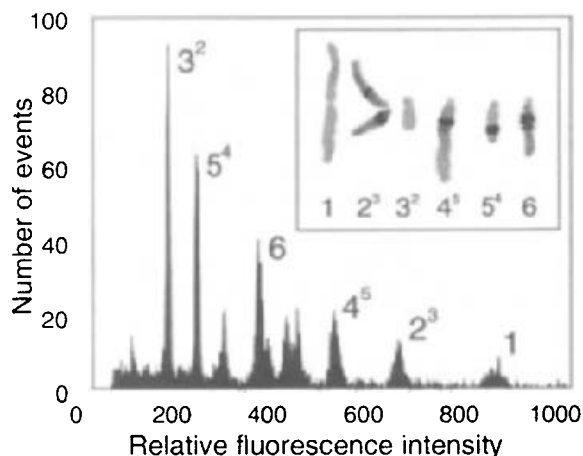

Figure 10-26. Flow karyotype of translocation line EF of broad bean (*Vicia faba* L.,  $2n = 12$ ) obtained after analysis of DAPI-stained chromosome suspension. All chromosome types are resolved into well-discriminated peaks. Insert: images of flow-sorted chromosomes. Sorted chromosomes were identified after fluorescent labelling of *FokI* repeats (dark bands). Courtesy of Jaroslav Doležel.

### Plant Chromosome Analysis and Sorting

Figure 10-26 shows a univariate karyotype of broad bean (*Vicia faba*). In the discussion of chromosome analysis and sorting on pp. 477-9, it was noted that, in many species in which chromosomes were similar in DNA content and base composition, it was necessary to work with lines containing chromosomal translocations to be able to sort material representing most of the karyotype. This procedure is frequently required in work with plants<sup>3066-7,3360-3</sup>; note that the chromosomes in Figure 10-26 come from a translocation line.

### Other Flow Cytometric Applications in Plants

Some stains, particularly acid dyes, behave differently in plant and animal cells; Calcofluor white M2R, for example,

works as an indicator of membrane integrity in animal cells but will stain cell walls of plant cells with intact cytoplasmic membranes, which lie inside the walls<sup>808</sup>. Bergonioux et al<sup>2014</sup> used acridine orange for DNA and RNA staining in nuclei isolated from plant protoplasts, and Ulrich<sup>2015</sup> described DAPI/sulforhodamine 101 staining for DNA and protein analyses in plant nuclei. Lucretti et al<sup>3364</sup> analyzed plant cell cycles using PI staining and antibodies to bromodeoxyuridine, and Taylor et al<sup>2718</sup> stained cellulose specifically (p. 363).

Measurements of the fluorescence of chlorophyll and other natural pigments as well as measurements of protein and nucleic acid content and specific antigens using extrinsic probes have been made in plant cells. Xu, Auger, and Govindjee<sup>1273</sup> measured chlorophyll fluorescence in isolated spinach thylakoids, and Pfündel and Meister<sup>3365</sup> used measurements of fluorescence above and below 710 nm to isolate maize mesophyll and bundle sheath chloroplast thylakoids.

Klock and Zimmermann<sup>2018</sup> used a flow cytometric assay to analyze the yield of fusion products in developing an improved method for electrofusion of plant protoplasts. Giglioli-Guivarch et al<sup>3366</sup> used BCECF to measure cytosolic pH of crabgrass mesophyll cell protoplasts, and O'Brien et al<sup>3367</sup> used Annexin-V and a TUNEL assay to monitor the progression of apoptosis in plants.

Wolters et al<sup>2019</sup> examined the origin of nuclear, chloroplast, and mitochondrial DNA in plant hybrids using a combination of flow cytometry and dot blot hybridization with DNA probes. Harkins et al<sup>2017</sup> examined gene expression in protoplasts isolated from transgenic tobacco plants by sorting; more recently, Galbraith<sup>2887,3368-9</sup> has led the move toward using GFP and its variants to study gene expression in plants.

### Microbiology, Parasitology and Marine Biology

As I wrote elsewhere<sup>3371</sup>, "Different people see microorganisms from different perspectives. To evolutionary and molecular biologists, microbes are relatives, with whom we set up correspondence. To biotechnologists, they are workers, to be employed and, perhaps, exploited. To environmental microbiologists, they may be merely scenery, or analogous to canaries in coal mines, but they are generally viewed as good neighbors if we have good fences. To clinical, food, and sanitary microbiologists, and to the defense establishment, microorganisms are enemies to be tracked, contained, and killed, and to leaders of rogue states and terrorist organizations, they are useful tools which are much easier to get through airports than are firearms and explosives."

It was van Leeuwenhoek's microscopy, in the 17th century, that first made us aware of the existence of the microbial world, but it was not until the advent of cytometry in the late 20th century that it became possible to carry out detailed studies of microorganisms at the single cell level. The motivation for doing this lies in the heterogeneity of microorganisms, which is far greater than the heterogeneity

of perspectives from which they are contemplated by human observers. Even closely related species may exhibit marked differences in biochemistry and behavior, and mutation rates are such that a colony of more than a few hundred thousand cells almost certainly contains genetically different individuals, so that striking heterogeneity can exist within a clonal population of organisms that, in the aggregate, occupy too little space to be visible to the unaided human eye. The importance of single-cell analyses in microbiology was stressed by Davey and Kell in 1996 in a comprehensive, indispensable review<sup>33</sup>.

In 2000, a special issue of *The Journal of Microbiological Methods* on "Microbial Analysis at the Single-Cell Level"<sup>2403</sup>, featured papers on flow and image cytometry and other techniques; the complete text of all articles is available free of charge online. An issue of *Scientia Marina* devoted to "Aquatic Flow Cytometry: Achievements and Prospects"<sup>2402</sup>, also appeared in 2000, and the July 1, 2001 issue of *Cytometry* was a special issue on "Flow Cytometry in the Marine Environment"<sup>3372</sup> (Volume 10, Number 5 of *Cytometry* (September, 1989) was a special issue on "Cytometry in Aquatic Sciences"). For those interested in alternative techniques, there is a 1998 book on *Digital Image Analysis of Microbes*<sup>2420</sup>.

### Measuring Microbes: Motivation

Microbiologists, whatever their perspective, subject specimens to cytometric analysis with well-defined goals in mind. In the simplest cases, it is necessary only that microorganisms be detected in a sample; at the next level of complexity, the organisms must be counted, explicitly or by the use of some surrogate indicator of the number present. Beyond this, an organism in pure culture may need to be identified and/or characterized as to its growth, metabolism, viability, and interaction with various chemical and physical agents. At the highest level of complexity, it may be necessary to detect, identify, count and characterize each of several organisms in a mixed population.

Even the simplest task, that of detection of microorganisms, may demand examination of several aspects of the specimen. As was mentioned in Chapter 3 (p. 74), **flow cytometric detection and counting of bacteria in air**<sup>29-31</sup> based on light scattering signals was demonstrated some time before similar technology was developed to deal with larger cells suspended in liquids. Detection becomes more difficult as the sample contains increasing amounts of inorganic or organic particulates in the microbial size range, making it necessary to use multiparameter approaches. As might be expected, gating measurements on the (relatively) strong scatter signal improve the signal-to-noise ratio in detection of immunofluorescently stained spores and bacteria<sup>914-5</sup>, and Mansour et al<sup>919</sup>, using a highly effective red cell lysing reagent and a centrifugation step, detected *Escherichia coli* seeded into human blood samples at concentrations of 10-100 organisms/mL by measuring forward scatter and ethidium fluorescence. Additional of parameters may further improve detection and identification; Donnelly and

Baigent<sup>916</sup>, for example, by combining forward scatter, propidium iodide, and fluorescein immunofluorescence, could detect *Listeria monocytogenes* in milk and discriminate this organism from several species of *Streptococcus* and *Staphylococcus*.

The first two generations of commercial fluorescence flow cytometers were not widely applied to studies of microorganisms. Early applications of flow cytometry to bacteria included fermentation process monitoring, industrial microbiology<sup>553,558,562,569</sup>, clinical diagnosis<sup>103,279,565-7</sup>, and environmental toxicology<sup>560</sup>. Preparative sorting was used to purify yeast basidiospores<sup>572</sup>, and to isolate microbial subpopulations with desired metabolic characteristics<sup>918</sup> following gene transfer.

Although interest in all of these areas (and the last is certainly not least) has increased, even now, fewer than two thousand of the tens of thousands of papers in the cytometry literature deal with microbiological applications. However, interest in this area is increasing. The first book devoted to flow cytometric applications in microbiology<sup>1052</sup> and another that devoted considerable space to the use of flow cytometry in marine microbiology<sup>1051</sup> are now out of print and, more to the point, out of date. I don't have enough pages available to do justice to the subject here; it is time for a new book, and I intend to start work on *Microbiological Applications of Cytometry* shortly after I finish this tome.

### Measuring Microbes: Instrument Issues

In principle, one can use a flow cytometer to measure the same parameters in bacteria or even viruses as are commonly measured in eukaryotic cells. In practice, since the size, mass, nucleic acid and protein content, etc. of bacteria are approximately 1/1,000 the magnitude of the same parameters in mammalian cells, it may be difficult to make good measurements, for two reasons. First, although modern instruments may reliably detect fewer than 1,000 molecules of fluorescent material in or on a cell, measurements at such low levels typically exhibit large variances due to photoelectron statistics; some microbial constituents may thus be undetectable or measurable with only limited precision. Second, flow cytometers designed with observation volumes large enough to permit precise measurements of eukaryotic cells have higher background levels of stray excitation light and Raman scatter than would an instrument designed explicitly for smaller particles.

However, when a properly designed or adapted instrument is used, sensitive and precise measurements can be made using light sources of modest power<sup>94,103,198,561,567,2915-6</sup>. Much of the earlier published work on flow cytometry of bacteria was done using custom-built or modified hardware; a lot of the rest was done on older Ortho systems, which, because observation was done in flat-sided cuvettes, had higher scatter sensitivity than did the stream-in-air instruments then produced by B-D and Coulter.

Among current commercial systems, the Lindmo/Steen arc source instrument<sup>100-3</sup>, commercialized by Skatron, later

sold as the Bryte HS by Bio-Rad, and now resurrected by Apogee, has excellent sensitivity for scatter measurements of microorganisms; the newest Apogee system, with a laser source, can easily detect medium- and large-sized viruses. Laser source instruments that make measurements in flat-sided cuvettes typically have somewhat better fluorescence sensitivity than arc source cytometers, but, while the cuvette decreases scatter noise compared to what would be observed in a stream-in-air system, the amplifiers for the signals produced by the diodes typically used to detect forward scatter may not provide enough gain to get signals from some smaller bacteria on scale.

Gant et al<sup>2077</sup>, who studied antibiotic effects on scatter and propidium fluorescence signals from *E. coli*, found an unmodified B-D FACScan sufficiently sensitive for their needs. However, Dusenberry and Frankel<sup>2076</sup> reported that modifying a FACScan by focusing the laser beam to a smaller spot and substituting a PMT as a forward scatter detector increased sensitivity almost fivefold, and Button and Robertson (D. Button and B. Robertson, personal communication) have done most of their work on bacterial sizing and DNA content determination<sup>686,2084,5,2092,2562-3</sup> with an Ortho system modified to provide a smaller (narrower) focal spot.

In instruments I have built for analyses of bacteria, I have modified the electronics to provide threshold setting on both scatter and fluorescence channels, so that the signals from both must be above threshold to trigger the front end electronics (pp. 191-2); I find this often makes the difference between being able to detect small organisms and not being able to detect them.

### Parameters Measured in Microorganisms

Forward and orthogonal light scattering, DNA and protein content, DNA base composition (A+T/G+C), lectin binding, membrane potential, and immunofluorescence measurements of **algae, bacteria, fungi, and protozoa** using flow cytometry had been reported in the literature by the mid-1980's<sup>103,197-8,279,552-73,701,914-26</sup>, as had autofluorescence of photosynthetic and other pigments. By the end of that decade, flow cytometric measurements of genetic probes<sup>1406-8</sup> had also been made.

What we know about the behavior of most of the reagents now common use in cytometry was learned largely from observation of the interaction of those reagents with eukaryotic cells. **The most important fact about microbial cytometry is this: bacteria are not just little eukaryotes.** Uptake of, and efflux of, dyes, drugs, and other reagents by and from bacterial cells are affected by the structure of the cell wall, and by the presence of pores and pumps that may or may not be analogous to those found in eukaryotes. It is inadvisable to conclude that even well-characterized dyes behave in bacteria as they do in mammalian cells, and unwise to assume that staining procedures that were developed for mammalian cells can be "ported," as the computer types say, to protists and prokaryotes with no modification.

Bonaly et al<sup>920</sup> noted that stationary cells of *Euglena* did not stain stoichiometrically for DNA with intercalating dyes such as ethidium, because chromatin structure changed sufficiently to decrease the number of binding sites. Hoechst 33258 did stain stationary cells stoichiometrically; stoichiometric staining with ethidium could be achieved using acid treatment to extract nuclear basic proteins. Kuchenbecker and Braun<sup>917</sup> found that DNA in ethanol-fixed yeast cells was stained effectively after 12 minutes' incubation in a solution containing 100 µg/mL olivomycin, 40 mM MgCl<sub>2</sub>, and 1 M NaCl; the DNA specificity of olivomycin eliminated the necessity for RNase treatment, which is critical when staining yeast cells with ethidium or propidium because of their high RNA content (does anyone else remember that RNA was once called zymonucleic acid?). Bernstein et al reported that internal antigens in *Dicystostelium* cells were better visualized by immunofluorescence when the cells were permeabilized with 0.1 mM digitonin than when the cells were fixed. More recently, Walberg et al<sup>3372</sup> found substantial, unpredictable variability in patterns of uptake of nucleic acid binding dyes by three species of Gram-positive bacteria; under some circumstances, staining intensity was greater when organisms were vitally stained than when they were fixed. It is therefore likely that application of a published cytometric technique to a new species or strain of will require empirical optimization of preparative methods.

In the brief discussion of parameter measurements and probes that follows, I will emphasize the current state of the art; the later sections on microbiological applications will also feature quirks, but may mention outmoded methodology.

### Flow Cytometric "Gram Stains"

The lipopolysaccharide **outer membrane of Gram-negative bacteria**, in its native state, presents a permeability barrier to most lipophilic materials<sup>2078-9</sup>; this is responsible for the resistance of the organisms to some antibiotics, and, from a cytometric point of view, also prevents staining of the intact organisms by many dyes. Chemical agents such as ethylene diamine tetraacetic acid (EDTA)<sup>2081</sup> may be used to permeabilize the outer membrane to drugs and dyes with at least transient retention of some metabolic function, although the characteristics of bacteria thus permeabilized are distinct from those of organisms in the native state. The properties of the outer membrane can be utilized in cytometric procedures analogous to Gram staining.

My initial approach to this<sup>2075</sup> was to use a single membrane potential dye, usually DiIC<sub>1(5)</sub>, to stain multiple aliquots of a sample. The first two aliquots have both dye and EDTA added; the EDTA insures that dye can enter both Gram-positive and Gram-negative bacteria, and it will be concentrated in bacteria if a membrane potential is present. The second aliquot also contains the proton ionophore CCCP, which reduces membrane potential to near zero. If there are particles with similar scatter signatures in both ali-

quots that are more fluorescent in the aliquot without CCCP than in the aliquot with CCCP, I conclude that they represent bacteria, because they have membrane potentials. I then examine a third aliquot, which contains dye but neither EDTA nor CCCP; this will show dye uptake if the organisms are Gram-positive but not if they are Gram-negative. This procedure correctly determined the Gram staining characteristics of a number of common organisms, including *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pyogenes* (Gram-positive), *Enterobacter cloacae*, *Escherichia coli*, *Klebsiella pneumoniae*, *Proteus vulgaris*, *Pseudomonas aeruginosa*, and *Salmonella typhimurium* (Gram-negative).

Molecular Probes has produced several kits containing fluorescent reagents for "Gram staining"; the LIVE BacLight kit contains two dyes excitable at 488 nm; the orange fluorescent hexidium iodide is analogous to ethidium bromide, but has a hexyl group instead of an ethyl group on the ring nitrogen, making it highly lipophilic, and the green fluorescent SYTO 9 is much more water soluble. Both dyes enter Gram-positive bacteria; hexidium is excluded by Gram-negative organisms with intact outer membranes and cytoplasmic membranes. The result is that Gram-positive organisms fluoresce red, while Gram-negative organisms fluoresce green. Mason et al<sup>3373</sup> correctly determined Gram staining status of 45 species using hexidium iodide and SYTO 13, a close relative of SYTO 9. Molecular Probes also offers fluorescent conjugates of **wheat germ agglutinin (WGA)**. In 1990, this lectin was reported by Sizemore et al<sup>3390</sup> to stain Gram-positive but not Gram-negative cells, and Molecular Probes licensed their patent; however, I could not find other accounts of the use of WGA for cytometric Gram staining in more recent literature.

### Detection and Sizing: Light Scattering

In the discussion of light scattering in Chapter 7 [pp. 275-6 (Figure 7-1) and 279-80], I emphasize the point that forward scatter signals from particles in the size range in which most eukaryotic cells lie are not precise indicators of cell size. However, I note on pp. 288-9 that scatter signals from bacteria and smaller particles can be used for sizing, and a number of groups have developed calibration procedures that allow cell volume to be computed from forward scatter signal intensity<sup>2540,2562,3,3374-5</sup>. For viruses and other particles in the size range below 0.2  $\mu\text{m}$ , side scatter signals may be preferable to forward scatter signals for sizing<sup>94,3376</sup>.

Scatter signal intensities depend on **refractive index** as well as on particle size; Green et al<sup>3377</sup> have described the use of flow cytometry to make measurements of both the size and the refractive index of phytoplankton organisms and marine particles.

Any mismatch of refractive index between the sheath fluid and the fluid in which cells are suspended adds noise to scatter measurements and may compromise accuracy<sup>3378</sup>. Even when scatter signals are only used for detection, it is advisable to correct index mismatches in order to maximize the chance of obtaining usable signals.

### Detection and Sizing: Electrical Impedance

DC Impedance (Coulter volume) measurements (p. 273) were used to detect and size bacteria<sup>680</sup> in the 1950's and viruses<sup>681,2525-9</sup> in the 1970's. Saleh and Sohn<sup>2530,3391</sup> have recently described microfluidic flow cytometric impedance measurement system that can size colloidal particles in the viral size range.

### Nucleic Acid (DNA and RNA) Staining

The number of ribosomes in a bacterial cell varies contain between a few hundred (in slowly growing organisms such as *Mycobacteria*) and tens of thousands (in metabolically active, exponentially growing *E. coli*). The content of double-stranded rRNA in most organisms is therefore several times the content of DNA. Dyes such as propidium and the SYTO and TO-PRO series, which form fluorescent adducts with both DNA and double-stranded RNA, will stain both; Guindulain and Vives-Rego<sup>3379</sup> found that at least two-thirds of SYTO-13 fluorescence in *E. coli* was due to dye binding to RNA.

While it is possible to treat fixed and permeabilized cells of at least some species with RNase or DNase, enabling nonselective dyes to be used for quantitative determination of DNA or the rRNA<sup>3380</sup>, it is difficult to get the enzymes into other species, making it prudent to use more selective stains.

Steen<sup>3381</sup> recommends the mithramycin-ethidium combination, DAPI, or the Hoechst dyes for staining DNA; the former requires deep blue or violet excitation (now more readily available from violet diode lasers), while the latter need UV excitation, at least in the context of analysis of microorganisms. Bernander et al<sup>3382</sup> found that all of these stains yielded histograms of equivalent quality in both an arc source (Skatron Argus) and a laser source (B-D FACStar) flow cytometer. Stefan Andreatta<sup>3383</sup> noted in his Doctoral Thesis (and in a posting to the Purdue List) that precision of histograms obtained with Hoechst dyes and DAPI is improved if a small amount of Na-citrate/K-citrate buffer is added to the sample prior to staining in order to bring the pH to about 7.5; this eliminates the yellow nonspecific fluorescence that is often observed when DAPI is used to stain bacteria.

For RNA staining, Borth et al<sup>3384</sup> used pyronin Y (which stains double-stranded RNA) in combination with methyl green, to block DNA staining; these authors also used Hoechst 33258 to stain DNA, but neither they nor anyone else seems to have reported the use of a combination of a Hoechst dye and pyronin Y for simultaneous DNA/RNA staining in bacteria. I would expect it to work.

Müller et al<sup>3385</sup> took a more radical approach to quantification of bacterial rRNA content; they stained cells with fluorescently labeled oligonucleotide probes for 16S and 23S rRNA. These, as will be noted presently, are better known for their utility in species identification.

### Total Protein Content: Scatter vs. Stains

Steen et al.<sup>103</sup> noted in 1982 that large-angle light scatter signals from *E. coli* cells stained for total protein with FITC were linearly correlated with fluorescein fluorescence signals. However, since there are some circumstances under which materials other than protein (e.g., gas vacuoles<sup>707</sup>) influence side scatter signals from bacteria, it is advisable to use a stain for critical analyses of total protein content. Zubkov et al.<sup>3386</sup> developed and validated a precise flow cytometric assay for measuring bacterial protein biomass using SYPRO dyes from Molecular Probes<sup>2332</sup>, which were originally intended for sensitive detection of proteins on gels. The intensity of SYPRO-protein fluorescence of marine bacteria strongly correlated with their total protein content as measured by the bicinchoninic acid method; according to the authors' calibration, the mean biomass of planktonic bacteria from the North Sea in August 1998 was 24 fg of protein/cell.

### Antibodies, Etc.: Labeling Strategies

If you happen to look in catalogs or compendia of antibodies, you will quickly discover a profound difference between bacteria and lymphocytes. Biotechnology has wiped out what used to be one of the bigger distinctions between the two; these days, bacteria can not only make antibodies, they can make better antibodies than lymphocytes can. But that's another story. I was hoping to call your attention to the fact that, while you can easily buy monoclonal antibodies to any of the many CD antigens found on lymphocytes, directly labeled with any one of a half-dozen or more tags, commercial monoclonal antibodies to bacterial and viral antigens are fairly scarce, and usually not available directly labeled. If you can find a directly labeled antibody, the odds are probably at least ten to one that the label is fluorescein.

There usually isn't a problem with fluorescein-labeled antibodies. However, if you happen to be looking at some species of *Pseudomonas*, you'll find they do a pretty good job of fluorescing at 525 nm in the absence of antibody. Similarly, you wouldn't want to use phycoerythrin to label an antibody against an antigen found in or on *Synechococcus*, which comes with an ample endogenous supply of the label. Vesey et al.<sup>2600</sup> described a procedure they used to select labels for detection of pathogens in water samples; by taking into account both the autofluorescence of particles in the water, and background fluorescence in the water itself, they were able to optimize signal-to-noise for stained specimens. It's a good model to follow; you will almost certainly be looking for many fewer antibody-binding sites on microorganisms than you'd be apt to find on eukaryotic cells, and you'll also need to pick labels carefully for nucleotide probes and other ligands.

While it is not generally a problem to get a fluorescent antibody that will identify a particular species or even a particular strain of bacteria, there are not antibodies that differentiate among larger groups of organisms, making it infeasible to develop a manageable panel of antibodies that could

be used to identify any of a large number of species. Ribosomal RNA probes offer an alternative.

### Ribosomal RNA-Based Species Identification

Various probes complementary to different sequences in 16S rRNA can distinguish among the primary kingdoms (Eukaryotes, Eubacteria, Archaeobacteria), and among smaller taxonomic groups, down to the species and strain level<sup>3392,3</sup>. Because many microorganisms cannot be grown in culture, it is desirable to be able to identify them without having to grow them; this can be accomplished using ribosomal probes. The several thousand ribosomes normally present per cell provide enough target sequences to make amplification unnecessary. Amann et al.<sup>1406</sup>, working with marine organisms, demonstrated the utility of 16S ribosomal RNA probes and flow cytometry for this purpose in 1990. The oligonucleotide probe technology has been improved since then, by optimizing probe sequences and binding conditions<sup>1407-8,3387,9</sup>; rRNA sequences have also been detected using peptide nucleic acid (PNA) probes<sup>2714,3394</sup> (p. 362), which allow cellular integrity to be better preserved and may provide stronger signals.

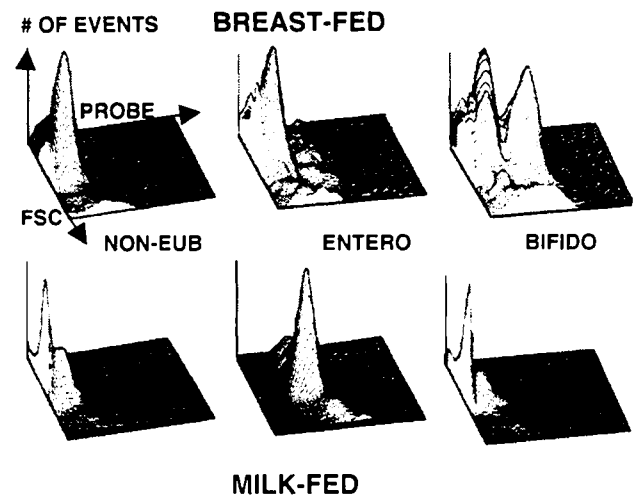

Figure 10-27. rRNA probe staining patterns demonstrate differences in enteric flora between breast-fed infants (top row) and infants fed reconstituted milk (bottom row). Left column: non-eubacterial probe; middle column: enterobacterial probe; right column: bifidobacterial probe. Courtesy of Vanya Gant (Hospital for Tropical Diseases, UCLH, London)

Figure 10-27 illustrates differences in the proportions of non-eubacterial organisms, enterobacteriaceae, and bifidobacteria in stool from breast-fed infants and from infants fed reconstituted milk. The same rRNA probe techniques work for the ecology of the gut<sup>3395</sup> and that of the ocean<sup>1456,3354</sup>.

### Functional Probes in Bacteria

Eukaryotes may maintain gradients of pH, membrane potential, and ion concentration across the membranes of

internal organelles such as mitochondria, lysosomes, and plastids; at least some organelles are believed to be descended from free-living ancestors resembling bacteria<sup>2255</sup>. Bacteria do not have complex systems of internal compartments, much of their metabolic activity occurs at the cytoplasmic membrane, and there are typically gradients of both pH and membrane potential across this membrane in viable, active cells.

### Membrane Potential, Permeability, "Viability," and Metabolic Activity

Kell et al<sup>2250</sup> presented a very thoughtful discussion of flow cytometry and its applications to the detection and quantification of metabolic, or functional, as well as structural heterogeneity in microbial cultures. They published a number of papers dealing with the flow cytometric determination of bacterial **viability**<sup>2251</sup>, **injury**<sup>2252</sup>, and **dormancy**<sup>2253,4</sup> using probes of **membrane potential** ( $\Delta\Psi$ ) and of **oxidative metabolism**.

I have already discussed membrane potential and its estimation by flow cytometry, in more detail than you probably wanted, on pp. 385-402; here, I will summarize points relevant and, in some cases, peculiar to membrane potentials in bacteria.

The outer membrane of Gram-negative bacteria, in its native state, presents a permeability barrier to the uptake of dyes, particularly lipophilic dyes such as cyanines and oxonols; however, when the cells are permeabilized with EDTA under conditions that preserve viability<sup>2081</sup>, these dyes will partition across the membrane as they do in other cells.

Unlike most of us, bacteria do not store large amounts of carbon and energy sources; this is one reason why nobody tries to sell them exercise equipment. As a consequence of this metabolic characteristic, bacteria lose their membrane potentials as soon as they use up the energy source in the medium. If an organism can grow on glucose and not on rhamnose, and you take its glucose away and give it rhamnose, the membrane potential drops to near zero within a few minutes. Put back glucose, or something else that will support growth, and the membrane potential comes back. Metabolically active bacteria have membrane potentials, more or less in the same way that metabolically active people have electroencephalographic waves.

Bacteria that are "dead" by **dye exclusion** criteria, that is, which let in propidium or the TO-PRO or SYTOX dyes, and/or won't retain fluorescein after FDA hydrolysis, are said to have lost **membrane integrity**. If one takes this to indicate the presence of a big hole or holes in the cytoplasmic membrane, loss of membrane integrity should result in the dissipation of ion concentration gradients across the membrane, with loss of the membrane potential. Membrane integrity, permeability, and "viability" have been discussed on pp. 299-303 and 369-371, and some relatively recent findings in bacteria may necessitate some rethinking of these concepts. Kell et al<sup>3454</sup> now equate "viability" and "culturability"; cytometry can measure "activity," but not "viability."

A great deal of bacteriology is dependent on being able to grow bacteria in culture. If we want to know whether there are bacteria in a supposedly sterile fluid, we put some into broth or onto an agar plate, incubate for some hours, and look for turbidity in the broth or colonies on the plate. Metabolically active bacteria will grow, when provided with the right nutrients, dead bacteria won't. However, there are also bacteria that may be **sublethally injured**, which basically means they look intact, but won't grow under normal conditions, and there are also bacteria that are **dormant**. Many bacteria and fungi are formal enough about dormancy so that they form **spores**, which exhibit little or no metabolic activity, but which are equipped to last for some time in inhospitable environments. Other bacteria, such as the *Micrococcus luteus* shown in the top panel of Figure 10-28, which came from a stationary phase culture in which their energy source was exhausted, simply cease metabolic activity; they lose membrane potential, but not membrane integrity. After nutrients are restored, such dormant organisms may regain metabolic activity, membrane potential, and the capacity to grow; the restoration of membrane potential following such resuscitation is evident in the bottom panel of Figure 10-28.

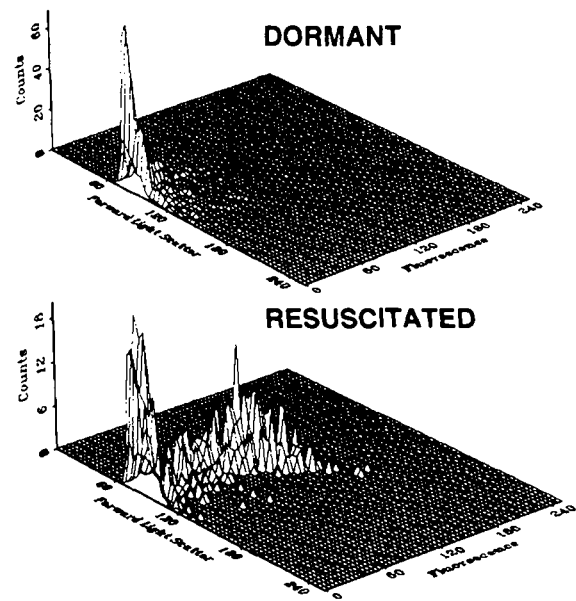

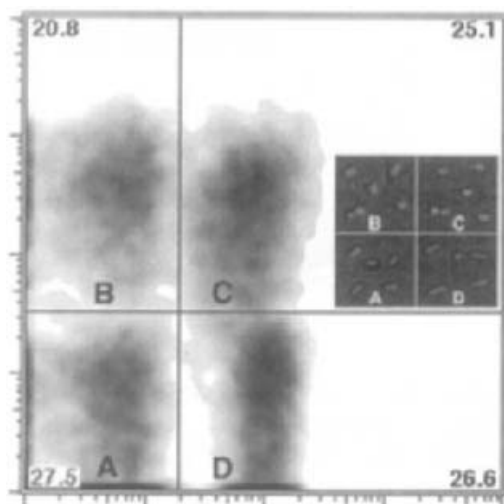

Figure 10-28. Membrane potential, as indicated by rhodamine 123 fluorescence, vs. forward scatter in dormant and resuscitated cultures of *Micrococcus luteus*. The figure was provided by Douglas Kell (University College of Wales, Aberystwyth; now at the University of Manchester Institute of Science and Technology).

Metabolic activity in the form of **respiration** in aerobic bacteria can be detected using an **indicator of oxidative metabolism** such as a **tetrazolium dye** (p. 379); Kaprelyants and Kell<sup>2252,2254</sup> used **cyanoditoyl tetrazolium chloride** (CTC), a fluorescent indicator with spectral characteristics

well matched to the arc lamp source in their Skatron instrument, for the purpose. They demonstrated that *M. luteus* cells that were frozen and thawed, causing a leakage of NADH from the cells, could regain respiratory activity, as indicated by reduction of CTC to an insoluble fluorescent formazan, when exogenous NADH was added to the medium. CTC was also used by Schaule, Flemming, and Ridgway<sup>2256</sup> to quantify respiring bacteria in drinking water with image analysis. Chromogenic tetrazolium dyes are widely used as indicators in microtiter plate assays of metabolic viability of both bacteria and mammalian cells.

Figure 10-29 illustrates the use of a combination of PNA rRNA probes and CTC to determine the fraction of metabolically *Salmonella typhimurium* in a mixed population of bacteria. A cocktail of non-*Salmonella Enterobacteriaceae* containing approximately equal numbers of *E. coli*, *C. freundii*, *P. vulgaris* and *S. dysenteriae* was prepared through volumetric mixing of cultures of known cell concentration. The mixture was divided in half and one portion killed with incubation in 10% buffered formalin for 30 min. Washed, formalin-killed cells were resuspended to their original volume in broth. Live and formalin-killed portions of *Salmonella typhimurium* were also prepared, and equal volumes of each preparation were combined to yield a final mixture containing four distinct populations: live (metabolically active) *Salmonella* (C), dead *Salmonella* (D), live non-*Salmonella Enterobacteriaceae* (B) and dead non-*Salmonella Enterobacteriaceae* (A). This mixture was incubated with CTC, fixed with formalin, hybridized with a Cy5-labeled *Salmonella*-specific PNA rRNA probe, and examined by flow cytometry.

*Salmonella*-Specific Fluorescence (Sal3-Cy5)

Figure 10-29. Combined rRNA probe and CTC staining for analysis of a genetically and metabolically complex cell mixture. Courtesy of Byron F. Brehm-Stecher and Eric A. Johnson, Food Research Institute, University of Wisconsin-Madison.

Believe it or not, a two-color analysis such as that shown in Figure 10-29 is fairly high-tech, as microbial cytometry goes. Two-angle scatter and one-color fluorescence was pretty much the norm for "multiparameter" cytometry of bacteria well into the 1990's, meaning that most people were only looking at one probe at a time.

While the CTC fluorescence shown in Figure 10-29 provides an indication that cells are, or at least were, viable, there wouldn't have been any way to confirm this, because the fixation required for rRNA probe hybridization killed the cells. Nebe von Caron<sup>2610</sup> and Hewitt<sup>3396</sup> and their collaborators have used single cell sorting of cells stained with multiple functional probes to confirm identification of cells as viable or nonviable, as illustrated in Figure 10-30.

*Salmonella typhimurium* stored for 25 days on nutrient agar at 4°C was re-suspended in buffered saline containing peptone, sodium succinate and glucose. Cells were treated with EDTA to allow dye penetration of the outer membrane, sonicated briefly to break up aggregates, and incubated with DiBAC<sub>4</sub>(3), ethidium bromide and propidium iodide for 30 min at 25°C. Cells were then sorted onto agar plates.

The lipophilic anionic oxonol dye DiBAC<sub>4</sub>(3) is used as a membrane potential probe; it stains electrically depolarized cells more brightly than cells that maintain membrane potential, and "permeabilised" cells, i.e., cells that have lost membrane integrity, brighter still, probably because of binding to hydrophobic regions in intracellular proteins. Ethidium enters the bacteria, but is actively pumped out by cells that maintain membrane potential. Intracellular ethidium enhances fluorescence on binding to double-stranded DNA or RNA. Propidium enters permeabilized cells and, because of its higher affinity for double-stranded nucleic acid (due at least in part to the extra positive charge; see pp. 306-7), displaces ethidium. DiBAC<sub>4</sub>(3) fluorescence is measured at 525 nm, and ethidium fluorescence at 575 nm.

The dye combination allows identification of cells in different functional stages. Active pumping cells do not stain significantly with any of the dyes. De-energized cells take up ethidium, but not DiBAC<sub>4</sub>(3) or propidium. Depolarized cells take up ethidium and DiBAC<sub>4</sub>(3), but not propidium, and permeabilized cells and "ghosts," with damaged membranes, take up both DiBAC<sub>4</sub>(3) and propidium.

Sorting of bacteria from different functional stages reveals that, in most cases, all but the permeabilized cells are capable of recovery. In the experiment shown in Figure 10-30, 35% of the electrically depolarized cells grew on agar plates; recovery was even better when cells were sorted onto special resuscitation media or into liquid media. Depolarization therefore is clearly not an indicator of decline in cell functionality, but certainly not cell death. Recovery of actively pumping and de-energized cells approaches 100% (de-energized cells lose pump activity but maintain membrane potential at least briefly); however, fewer than 1% of events sorted from the regions containing permeabilized cells and ghosts form colonies on agar.

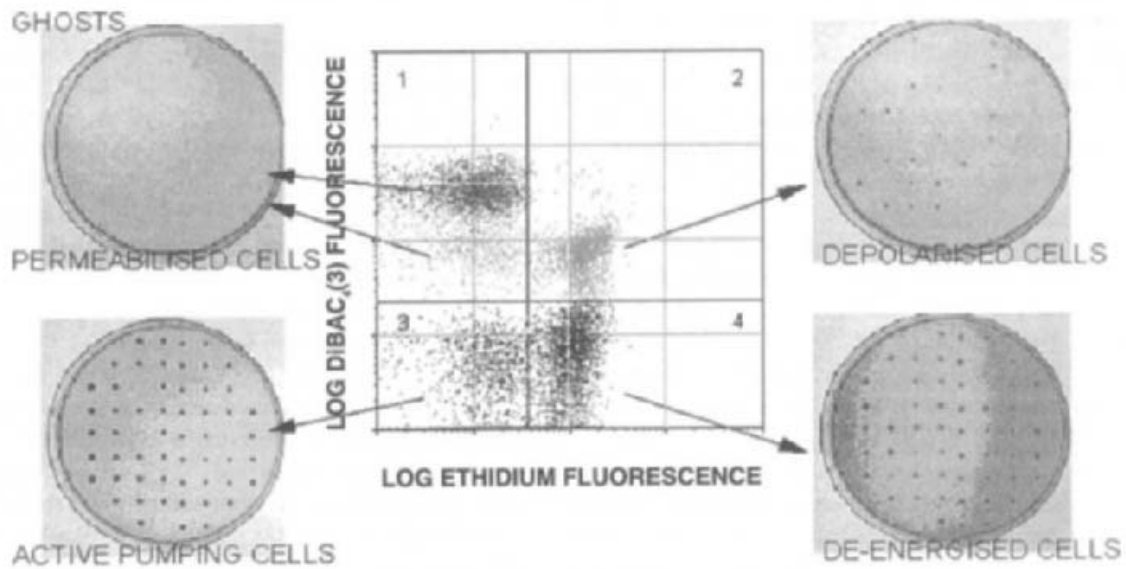

Figure 10-30. Recovery of *Salmonella typhimurium* in different functional states determined by staining with DiBAC<sub>4</sub>(3), ethidium bromide, and propidium iodide. Courtesy of Gerhard Nebe-von-Caron (Unipath, Ltd.).

Life (and death) get still more complicated, as can be appreciated from Figure 10-31, below.

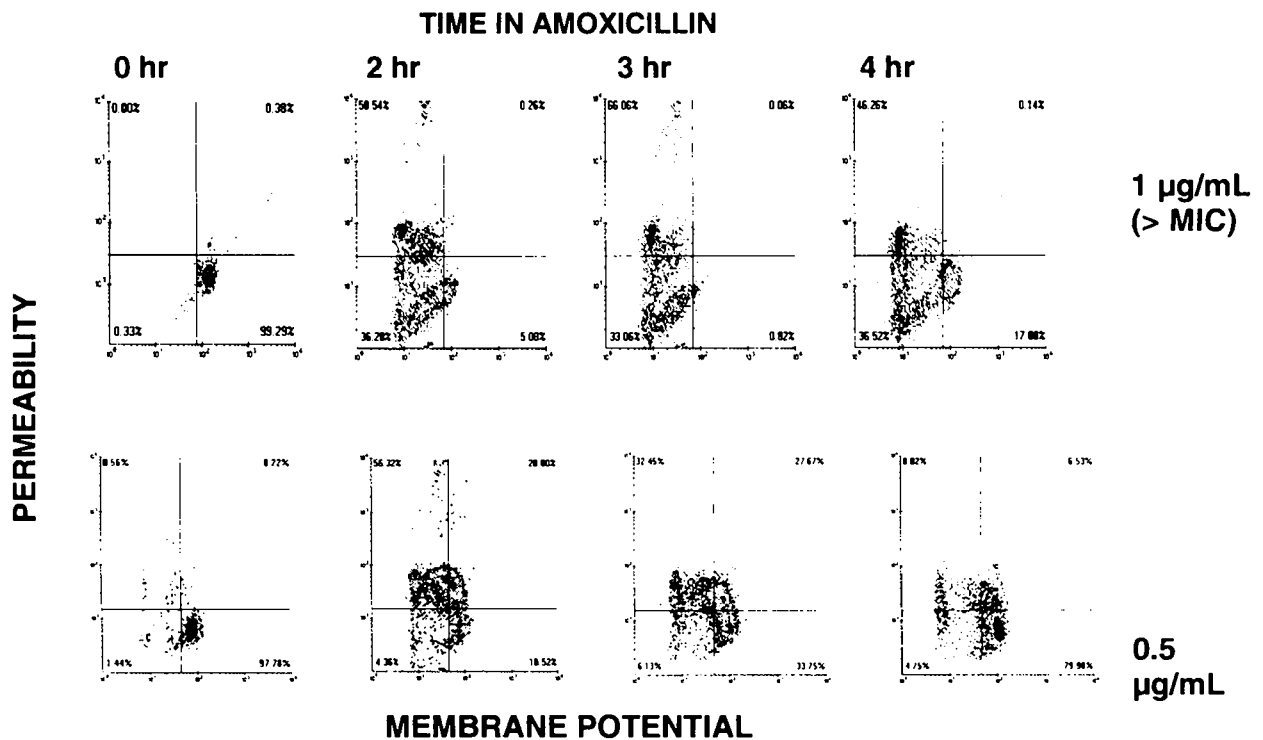

Figure 10-31. Effects of amoxicillin on membrane potential ( $\Delta\Psi$ ) and permeability of *Staphylococcus aureus*, measured ratiometrically using DiOC<sub>2</sub>(3) and TO-PRO-3<sup>2351,2357</sup>.

After we developed the ratiometric membrane potential measurement method<sup>357</sup> described on pp. 400-2, David Novo, Nancy Perlmutter, Richard Hunt and I turned our attention to multiparameter measurements of membrane potential and permeability in bacteria exposed to antibiotics<sup>351</sup>. We used a cytometer with 488 and 633 nm lasers for measurements of bacteria exposed simultaneously to our membrane potential indicator dye, DiOC<sub>2</sub>(3), and TO-PRO-3. Figure 10-31 plots the ratiometric membrane potential (red/green DiOC<sub>2</sub>(3) fluorescence) of amoxicillin-treated *Staphylococcus aureus* against a ratiometrically normalized permeability measure, i.e., the ratio of TO-PRO-3 fluorescence to green DiOC<sub>2</sub>(3) fluorescence. The ratiometric permeability measurement removes most of the effects of cell size variation and clumping in the same way as is accomplished by the ratiometric  $\Delta\Psi$  measurement.

The strain of *S. aureus* we used was amoxicillin sensitive, but we exposed it to concentrations of amoxicillin above (1  $\mu\text{g}/\text{ml}$ ) and below the minimal inhibitory concentration (MIC). In cultures treated with either dose, at time zero, most cells show low values of permeability and relatively high values of  $\Delta\Psi$ , appearing in the lower right quadrant of the display. After 2 hr at an amoxicillin concentration above MIC (top strip), many cells have lost  $\Delta\Psi$  completely, and almost all have lost  $\Delta\Psi$  to some extent, appearing in the lower and upper left quadrants; over 58% of the total have become permeable (upper left quadrant). By 4 hr, some regrowth has occurred; about 17% of the events measured show normal  $\Delta\Psi$  and no permeability. The situation is quite different at an amoxicillin concentration below MIC (bottom strip). At 2, 3, and even 4 hr, a substantial fraction of events (as high as 28%) are in the upper right quadrant, indicating a membrane potential greater than zero with permeability to TO-PRO-3. By 4 hr, most cells (over 79%) have regained normal  $\Delta\Psi$  and lost permeability. Bacterial counts were followed over this time period, which was too short to have allowed a high- $\Delta\Psi$ , impermeable population to appear due to growth of the small population of such cells present after 2 hr. Although it is possible that some intermediate- $\Delta\Psi$ , permeable events represent aggregates of high- $\Delta\Psi$ , impermeable viable cells and permeable, low- $\Delta\Psi$  dead cells, it appears that many of these events are accounted for by transiently permeabilized viable cells.

The phenomenon of transient membrane permeability induced by sublethal injury thus appears to be real, and may be quite general; we have since observed it in *Pseudomonas aeruginosa* and *Escherichia coli* as well as in *S. aureus*<sup>357,359</sup>, and others (*S. Barbesti*, personal communication; G. Nebevon-Caron, personal communication) have also encountered it. Amor et al<sup>358</sup> noted propidium uptake in the presence of carboxyfluorescein retention in sublethally injured *Bifidobacterium* species; their paper also described an effective ratiometric  $\Delta\Psi$  measurement technique using the ratio of DiBAC<sub>4</sub>(3) fluorescence to side scatter, but they apparently did not examine cells simultaneously stained with DiBAC<sub>4</sub>(3) and propidium.

## Digression: A Therapeutic Approach Based on Transient Permeabilization

Our primary conclusion, based on substantial differences in patterns of membrane potential and permeability responses of different microorganisms to different antibiotics<sup>351</sup>, was that a simple, rapid, "one-size-fits-all" flow cytometric test for bacterial antibiotic susceptibility, long sought by ourselves and others, was likely to be unattainable, although multiparameter cytometry seemed well suited to dissecting these distinct responses in the context of development of new antimicrobial agents.

Several months later, it occurred to me that, if multiply resistant bacteria that could not be killed by an existing combination of agents could be transiently permeabilized, it would be possible to derivatize a large number of generally toxic heterocyclic compounds [e.g., by adding the quaternary ammonium groups that differentiate propidium from ethidium (p. 300)] to forms that would be taken up by, and kill, the permeabilized bacteria, while not entering host cells. This formed the basis for a successful patent application (U.S. 6,562,785, May 13, 2003); I now have some evidence (unpublished) that TO-PRO-3 itself can kill bacteria if transported in, and am looking for the right pharmaceutical industry partner for an intensive development project.

Investigators who previously used flow cytometry to study the interactions of antimicrobial agents and bacteria<sup>2263,3371,3395-403,3479,3488</sup> typically measured only a single parameter, usually membrane permeability or membrane potential in attempts to determine "viability"; although their results correlated fairly well with classical susceptibility tests, they did not establish cytometric criteria for viability on a cell-by-cell basis, and could not have detected transient permeabilization. One take-home message is that it is always a good idea to measure multiple parameters when you're not sure what's going on. Another is that, even now, drug leads don't always come from combinatorial chemistry, genomics, or proteomics; the promising therapeutic approach described above may be one of the first to emerge from **cytomics**, and making it work, or finding out that it won't, will require some fairly sophisticated cytometry. I'm ready.

## So Few Molecules, So Little Time: Viruses

Even with three beams and twelve colors, conventional flow cytometers cannot give us as much information as we would like to have about microorganisms. When we are trying to detect signals from only a few thousand, or a few hundred, or a few dozen fluorescent molecules, the typical observation time of a few microseconds is simply not long enough for us to collect enough photons to get precise measurements.

If we stain DNA with a Hoechst dye, we can expect at most 1 dye molecule per 4 A-T base pairs at a saturating dye concentration. If that DNA is in *E. coli* (roughly 50% A-T), an organism with 2 copies of the chromosome (roughly 9.2 million base pairs) will bind at most 1.15 million dye

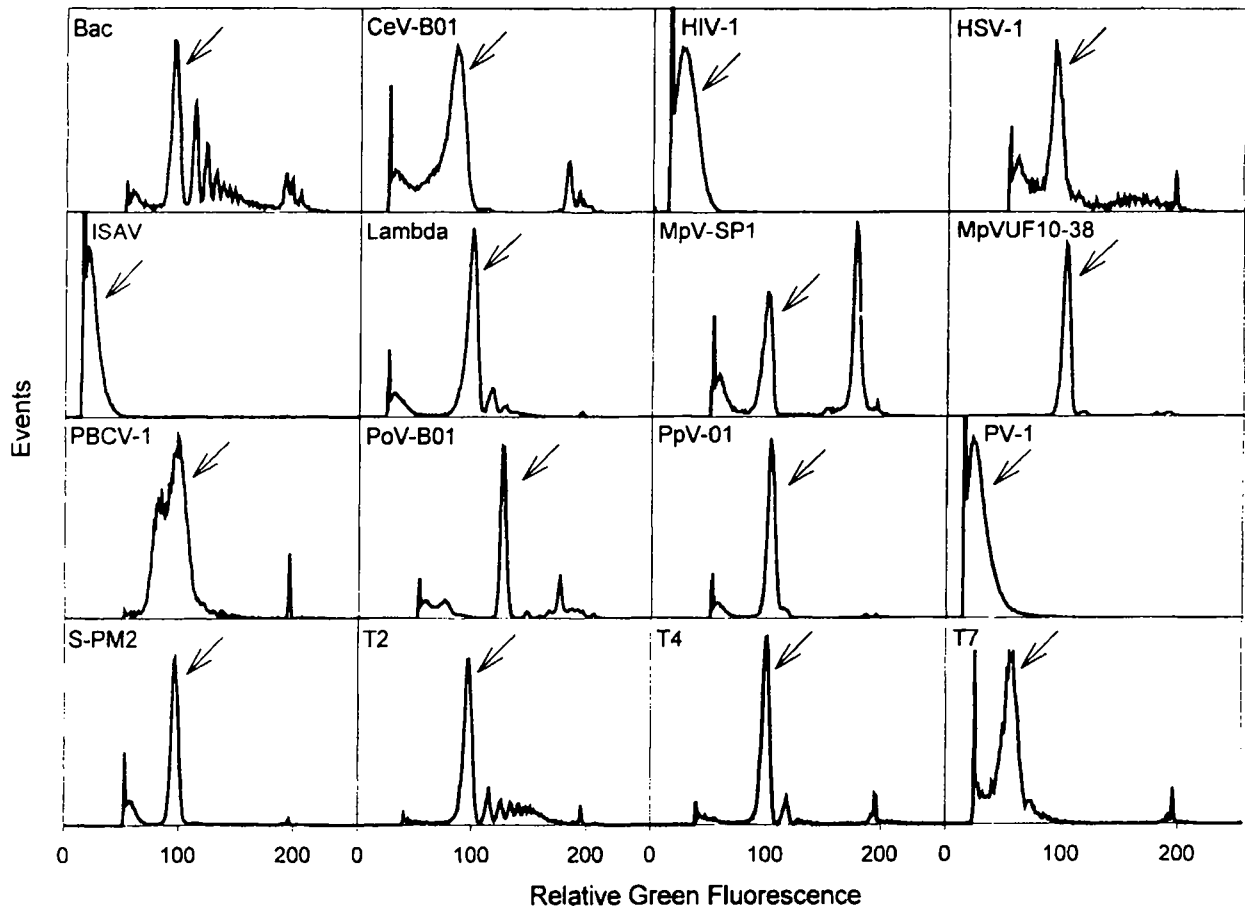

Figure 10-32. Fluorescence profiles of viruses stained with SYBR Green I. Peaks indicated by arrows represent individual virions; the highest intensity peaks (clearest in the panel showing PBCV-1) represent 0.95  $\mu\text{m}$  fluorescent beads. Key: Bac, a baculovirus; CeV-B01, MpV-SPI, MPVUF10-38, PoV-B01, PpV-01, algal viruses; HIV-1, human immunodeficiency virus; HSV-1, Herpes simplex virus; ISAV, infectious salmon anemia virus; Lambda, T2, T4 and T7, bacteriophages; PBCV-1, a virus infecting *Paramecium* and *Chlorella*; PV-1, poliovirus; S-PM2, a virus infecting *Synechococcus*. Reprinted from Brussaard CPD, Marie D, Bratbak G: Flow cytometric detection of viruses. *Journal of Virological Methods* 85:175-82 (reference 2337), Copyright 2000, with permission from Elsevier Science.

molecules, all of which should have the relatively high quantum efficiency they acquire on binding. If, in our brief observation time, we can generate one photoelectron at the fluorescence detector PMT cathode for each 100 dye molecules, we'll get 10,000 photoelectrons from each cell; the CV of the measurement in an otherwise perfect instrument will therefore be no lower than 1 percent. CV values reported by Bernander et al.<sup>3382</sup> for Hoechst 33258-stained *E. coli* with 2 copies of the chromosome were around 6 percent, indicating that measurement precision was not limited by photoelectron statistics. CVs for cells with 8 chromosomes, stained with Hoechst 33342 or DAPI, were under 3 percent.

Most bacteria contain several times as much double-stranded rRNA as DNA; we should therefore get strong, if not specific, signals from bacteria stained with TO-PRO-, SYTO-, or SYTOX dyes. However, when we attempt to detect nucleic acid in viruses using conventional flow cytometers<sup>2337</sup> (Figure 10-32), we can expect problems, for a number of reasons.

The genome sizes of the viruses studied by Brussaard et al.<sup>2337</sup> range from 9.2 to 300 kbp, but it is probable that, in many cases, the compact structure of the virion will limit access of dye to the viral nucleic acid, reducing the number of available binding sites. Also, while dye should bind to accessible double-stranded viral DNA and RNA more or less as it binds to DNA in prokaryotes and eukaryotes, it is not clear how well dye will bind to single-stranded viral nucleic acid, nor how much fluorescence enhancement will occur as a result of binding. If we extracted the naked DNA of a dsDNA virus with a 50 kbp genome, such as bacteriophage lambda, we would expect to be able to bind no more than about 6,000 molecules of a Hoechst dye to the nucleic acid; this would generate about 60 photoelectrons at the fluorescence detector of a conventional flow cytometer.

Hoechst dyes typically increase fluorescence by a factor of about 100 on binding to nucleic acid. In a conventional flow cytometer, fluorescence is collected from a volume of approximately 10,000 fL ( $10^{-11}$  L). The virion will occupy a

volume less than 1 fL. If the concentration of dye used is 3  $\mu\text{M}$ , there will be  $1.8 \times 10^7$  molecules of unbound dye in the observation volume. Since the quantum efficiency of unbound dye is 1/100 that of bound dye, we should generate 1 photoelectron for every  $10^4$  molecules of free dye. We are then trying to find the 60 photoelectrons generated by the virion in the company of 1,800 photoelectrons resulting from detection of fluorescence of free dye. Poisson statistics tell us that 1,800 photoelectrons are really  $1,800 \pm (1,800)^{1/2}$ , or  $1,800 \pm 42$  photoelectrons, so we will, at best, barely be able to detect a molecule of viral DNA above background. This gives us a signal to noise ratio near 1, which translates to a CV near 100%.

The data in Figure 10-32 could not have been collected using a Hoechst dye; the dye used was SYBR Green I, which increases fluorescence almost a thousandfold on binding to nucleic acid, and has a higher quantum efficiency when bound than do the Hoechst dyes. Using this dye, we'd probably get 120 photoelectrons from the DNA molecule, and no more than a few hundred from the background, making the nucleic acid easily detectable. Brussaard et al.<sup>2337</sup> did not find a strong linear relationship between staining intensity and genome size in the viruses they worked with, suggesting that dye access to nucleic acid is somewhat restricted, but enough dye apparently bound to viral nucleic acid to allow fluorescence signals from all but the small-genome RNA viruses (HIV-1, ISAV, and polio) to be clearly discriminated from background.

Now turn your attention back to pp. 471-3 and Figure 10-10. The panel in the upper left corner of that figure shows the intensities of fluorescence signals from bacteriophage lambda DNA, and from fragments of that DNA as small as 564 bp. The peaks from the intact DNA and the larger (> 5 kbp) fragments) appear to have fairly low CVs. What's the trick? The trick is that the observation time on Rob Habbersett's slow-flow instrument at Los Alamos, from which the data were obtained, is a few milliseconds, rather than a few microseconds, meaning that, all other things being equal, a given chunk of DNA generates about 1,000 times as many photoelectrons in the slow-flow instrument as in a conventional flow cytometer.

We can measure DNA adequately in bacteria in a conventional instrument; we can also, as the calculation on p. 402 shows, get reasonable, if not spectacular, statistics in the ratiometric membrane potential measurement, in which we pack a whole lot of dye into the bacteria. If we're interested in measuring immunofluorescence, or nucleic acid probes (even rRNA probes), or in ratiometric measurements of pH (see p. 407) or calcium, we'll have to use longer observation times if we want decent precision. The manufacturers don't seem to be in a big rush to make instruments with the appropriate performance characteristics.

### Applications in Marine Microbiology

Since life started in the ocean, it seems appropriate to start my detailed review with marine microbiology. A rapidly

growing body of cytometric literature deals with **marine microorganisms**, which include **bacteria**, **phytoplankton**, **zooplankton**<sup>570, 1,686, 707, 927-32, 105, 2536, 7,3404,6</sup>, and, most recently, **viruses**

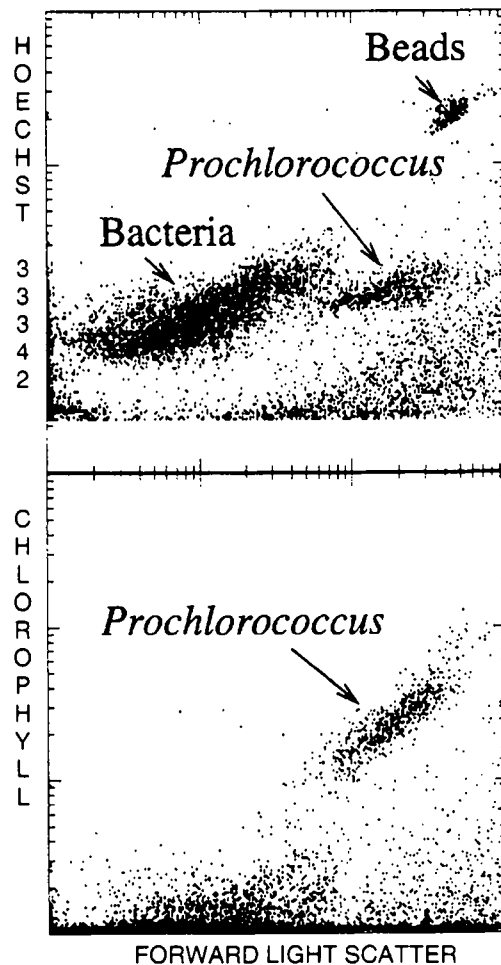

Figure 10-33. Forward scatter, Hoechst 33342 (DNA), and chlorophyll fluorescence (all on log scales) of the recently discovered marine bacterium *Prochlorococcus*<sup>2272</sup> measured with a dual-beam flow cytometer. The figure was provided by Brian Binder, Sallie Chisholm, Sheila Frankel, and Robert Olson (M.I.T. and Wood's Hole Oceanographic Institution).

Figure 10-33 shows the flow cytometric signature of the marine bacterium *Prochlorococcus*, discovered with the aid of a flow cytometer by Chisholm et al in 1988<sup>2272</sup>. The UV-excitable beads in the top panel are 0.46  $\mu\text{m}$  diameter spheres from Polysciences; 0.57  $\mu\text{m}$  yellow-green fluorescent beads from the same supplier are off scale on the bottom panel. There's a lot of *Prochlorococcus* in the ocean<sup>3407,5</sup>; according to Zubkov et al<sup>3410</sup>, almost a third of the total bacterioplankton turnover of amino acids can be attributed to the species.

*Prochlorococcus* isn't the only new species flow cytometry has helped discover. In July, 1994, Courties et al<sup>7063</sup> reported the discovery of the smallest known eukaryotic organism, a

green alga named *Ostreococcus tauri* which is the main component of the phytoplankton in the Mediterranean Thau lagoon of France. *Ostreococcus*, at 0.97 by 0.70  $\mu\text{m}$ , may be bigger than *Prochlorococcus*, but, for a eukaryote, it's tiny. It has one plastid and one mitochondrion, and its DNA content is about 33 fg.

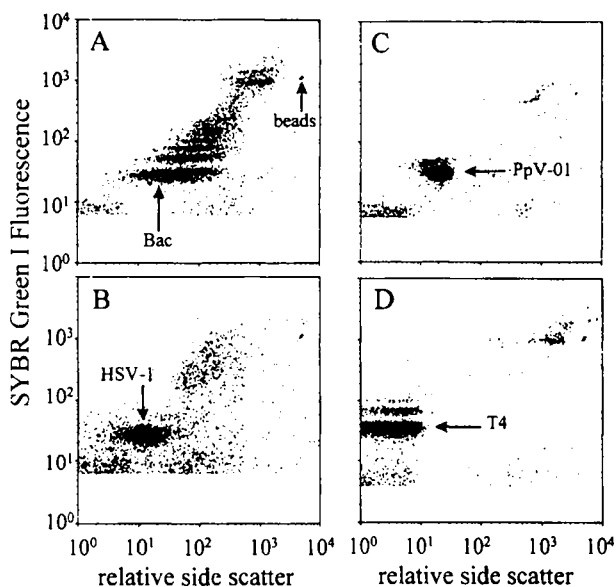

Figure 10-34. Side scatter and fluorescence signatures of four viruses shown in Figure 10-32. Reprinted from Brussaard CPD, Marie D, Bratbak G: Flow cytometric detection of viruses. *Journal of Virological Methods* 85:175-82 (reference 2337), Copyright 2000, with permission from Elsevier Science.

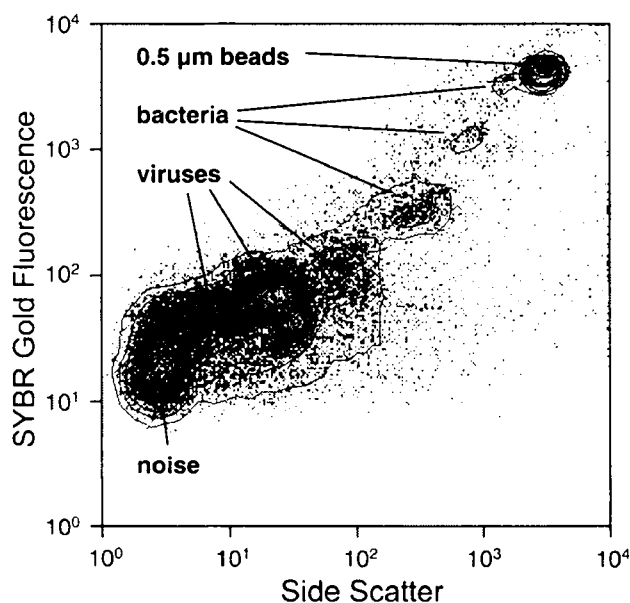

Figure 10-35. Side scatter and fluorescence signatures of particles in a water sample from a small Alpine pond. Courtesy of Stefan Andreaatta (University of Innsbruck).

The new mystery guests in the aquasphere are viruses. Figures 10-34 and 10-35 show scatter signals from cultured viruses<sup>2337</sup>, including the algal virus PpV-01, and from a sample of pond water that contains bacteria and viruses<sup>3406</sup>. The data in Figure 10-35 are particularly impressive; they were collected from a stream-in-air (MoFlo) sorter with the drop drive on!

Before the previous edition appeared, Troussellier, Courties, and Vaquer<sup>2086</sup> reviewed applications of flow cytometry in marine microbial ecology, which include identification of organisms<sup>2087-8</sup>, determination of biomasses and productions<sup>2089-92</sup> and the measurements *in vitro* of bacterial and phytoplanktonic growth<sup>2093-8</sup> and metabolism<sup>2099-1180</sup>. Monfort and Baleux<sup>2101</sup> found flow cytometry reliable as compared to epifluorescence microscopy for counting bacteria in aquatic ecosystems. Balfourt et al<sup>2140</sup> compared the performance of a laboratory-built and a commercial flow cytometer in phytoplankton analysis. Monger and Landry<sup>2102</sup> compared Hoechst 33342 and DAPI for staining DNA in marine bacteria, and found lower background and lower CV's with the Hoechst dye. Other authors<sup>2103-4</sup> considered aspects of scatter and absorption by phytoplankton cells, and applications of flow cytometry to characterizing organic<sup>2105</sup> particles in water. Flow cytometry has also been used to study larger organisms' feeding on smaller ones<sup>1605-8</sup>. At the high end of the size scale, Le Gall et al<sup>2106</sup> measured DNA content and base composition of macroalgal nuclei. Intracellular toxin was determined flow cytometrically in the marine dinoflagellate *Gonyaulax*, which causes "red tide"<sup>571</sup>, and flow cytometric quantification of the autofluorescence of luciferin in this organism was used to study the circadian cycle of its bioluminescence<sup>2049</sup>; DNA content analyses<sup>2040-1</sup> established the periodicity of the *Gonyaulax* cell cycle.

Good collections of papers on cytometry and marine biology appear in recent special issues of *Scientia Marina*<sup>2402</sup> and *Cytometry*<sup>3372</sup>.

Multiangle light scattering, autofluorescence, and DNA content<sup>197-8,570</sup> have all been used as identifying parameters for phytoplankton, with rRNA probes added to the mix as the technology improved<sup>3394,3408,3411-3</sup> (the fishing grounds may be alarmingly depleted, but there's still plenty of FISH in the sea), and flow cytometry has become a standard method for monitoring phytoplankton population dynamics. Although several Coulter EPICS instruments made ocean voyages<sup>928</sup> (I haven't heard them called EPICS Seas), they and other large instruments were/are not really optimized for phytoplankton analysis; most groups now use benchtop flow cytometers.

Quantification of the types and numbers of microflora and -fauna in the oceans should provide a sensitive means of monitoring changes in the quality of the environment. Figure 10-36 is directly related to this issue; it was provided by Don Button and Betsy Robertson of the University of Alaska, who used a modified Ortho instrument<sup>2089</sup>. Panel A shows a mixed bacterial population obtained from Prince William Sound, site of the 1989 *Exxon Valdez* oil spill<sup>2085</sup>; Panel B shows a seawater culture inoculated with gravel

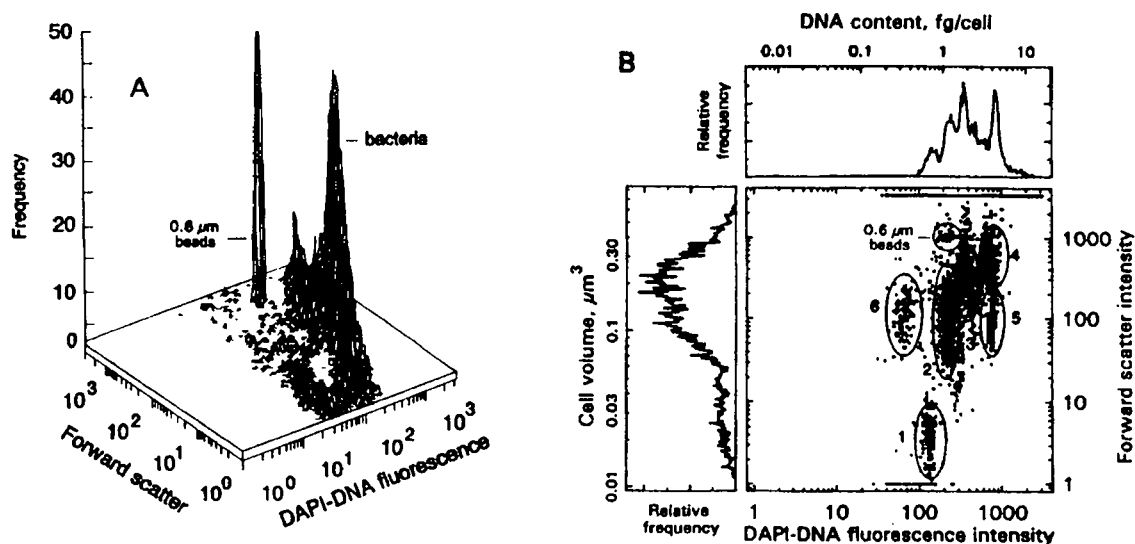

Figure 10-36. Size and DNA content of bacteria in seawater from Prince William Sound, Alaska (A), and of bacteria in a culture growing on a crude oil/terpene mixture (B). The figure was provided by Don Button and Betsy Robertson (U. of Alaska). Note that the scales express parameter values, not arbitrary numbers.

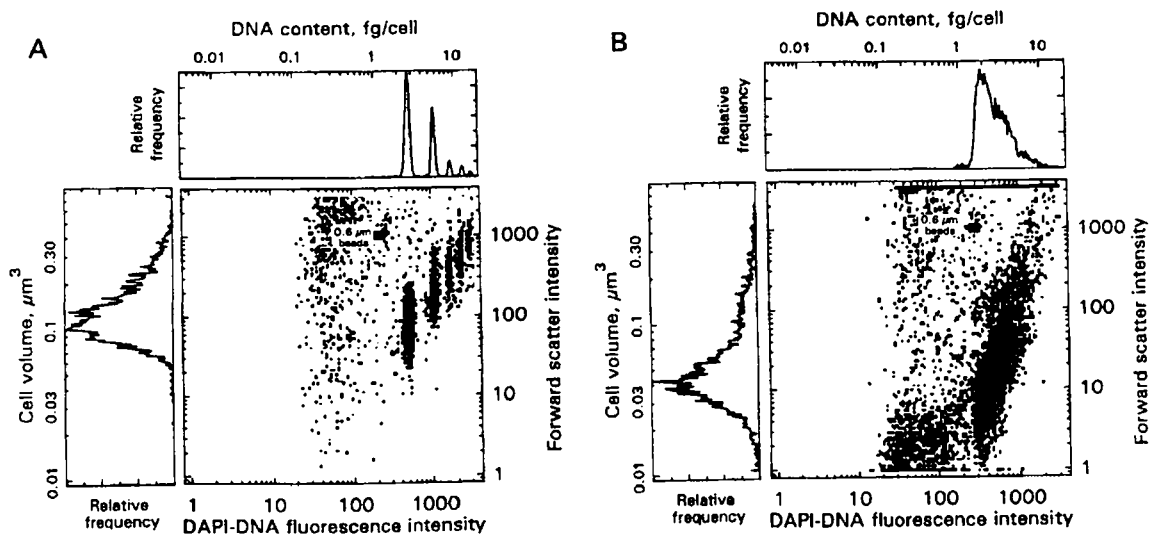

Figure 10-37. Size and DNA content of *Oligobacterium* RB1 isolated from Resurrection Bay, Alaska (A), and of the indigenous population from which RB1 was isolated (B). From Don Button and Betsy Robertson.

using a crude oil/terpene mixture as a carbon source. Some organisms will metabolize anything.

All kidding aside, Figure 10-36 and Figure 10-37, which came from the same place, exemplify a practice that ought to be more widespread in flow cytometry. Note that the scales on the histograms and dot plots are given in fg/cell DNA content and cell volume in  $\mu\text{m}^3$  (fl), not channel numbers or arbitrary powers of ten. The volumes are derived from Mie theory<sup>2562-3</sup>, and normalized with respect to the forward scatter signal and known Coulter volume for *E. coli*; the DNA scale was obtained from a standard curve of *E. coli* treated with rifampicin to produce cells with different integral numbers of genomes. The cells were stained with DAPI,

which is A-T specific; the DNA content scale assumes the 50% G-C content characteristic of *E. coli*. If the organisms involved have a substantially different G-C content, the number is off; however, the scale remains consistent, and G-C content variations can be corrected for<sup>3416</sup>. Maybe if the journals gave notice that scales such as these would be mandatory in two years, the rest of us would get motivated.

Figure 10-37 shows DNA content and cell volume of microorganisms isolated from Resurrection Bay, near Seward, Alaska. Panel A shows the growth pattern at fast growth rates of *Oligobacterium* RB1 isolated by extinction culture; there are cell subpopulations with different numbers of copies of the genome. Panel B shows the signature of the in-

digenous population of microorganisms from which RB1 was isolated. I really appreciate these figures, because I wrote parts of the previous edition on board ship in both Prince William Sound and Resurrection Bay, on what was supposed to be a vacation to celebrate finishing the manuscript. I did get to observe some interesting marine microbiological phenomena; the toilets ran on seawater, and, late at night, the bioluminescent organisms would put on their own little light show. When you flushed, they flashed; it was like the Fourth of July.

Flow cytometry of marine microorganisms involves very long runs and accumulates huge amounts of data. Multivariate data collection and analysis<sup>2107-8</sup> are essential for discrimination of multiple species in samples; it is generally felt that automated on-line analysis, e.g., by neural networks<sup>1215-6,2503-4,3417-20</sup> will ultimately be necessary to keep up with the amount of data generated, particularly as more parameters are measured.

### Extensions: Cytometers for Marine Applications

In the 1980's, Dubelaar et al<sup>695,1167-8</sup> described the Optical Plankton Analyzer, a multibeam instrument with slit-scanning capability optimized for analysis of a wide size range of marine organisms; also around that time, I helped Penny Chisholm, Rob Olson, Sheila Frankel et al, at M.I.T. and the Woods Hole Oceanographic Institution, build somewhat simpler cytometers<sup>198,2082</sup>.

The latest instruments from Dubelaar are the CytoBuoy<sup>2566,2910</sup> series, commercially available from **CytoBuoy, b.v.** (see p. 430); they are designed to be mounted on buoys or in submersible vessels, and incorporated sophisticated, miniaturized optics and electronics with low power consumption. Detector signals may be telemetered to a remote monitoring computer. **Fluid Imaging Technologies** (pp. 168 and 431) offers the FlowCam<sup>2453</sup> imaging flow cytometer, which, like the CytoBuoys, can accommodate larger particles than most flow cytometers.

Cavender-Bares et al<sup>3414</sup> modified a Coulter EPICS V flow cytometer to allow rapid switching between single- and dual-sheath fluidic systems, making it possible to achieve optimal conditions for analysis of a wider range of size classes and concentrations of plankton organisms than would be possible using a conventional instrument.

Olson et al<sup>3415</sup> describe a microfluorimeter and a flow cytometer using the "pump-during-probe" technique, which measure chlorophyll fluorescence yield of phytoplankton cells following excitation by a pulsed argon laser. They have also built a submersible flow cytometer; for details, see: <http://www.whoi.edu/science/B/Olsonlab/>

Trask et al<sup>197,211</sup> pointed out that the excitation spectrum of autofluorescence from algal phycobiliprotein photosynthetic pigments<sup>927,929</sup> is extremely useful for identification; a multistation flow cytometer, with excitation beams at blue, green, yellow, and red wavelengths, suitable for excitation of algal phycobiliprotein pigments would be the ideal apparatus to use on phytoplankton analysis, because it

should improve discrimination of species in unstained samples. This could now be implemented with small enough lasers to fit the apparatus comfortably on board a ship, but I haven't heard of anybody doing it.

### References: Flow Cytometry and Oceanography

Claude Courties, Marc Troussellier and Louis Legendre, of the Observatoire Océanologique, Banyuls-sur-Mer, France, maintain an online list of references on flow cytometric applications in oceanography. The list is regularly reviewed, and can be consulted and downloaded at <http://www.obs-banyuls.fr/FCM-Oceanography/Database.html>; as of February 24, 2003, it contained 447 references.

### General Microbiology

#### Previously Noted

As reported in the previous edition, Madelin and Johnson<sup>2109</sup> used an aerosol particle counter to size fungal and actinomycete spore aerosols at different humidities; this was a good way to commemorate the Golden Anniversary of the Gucker experiments.

Numerous authors<sup>1514-5,2127-39</sup> have used flow cytometry to measure binding of labeled antibodies to bacterial cell surfaces, for purposes as varied as determining levels of antibodies in serum and analyzing the structure of transmembrane proteins (p. 479). Nelson, Neill, and Poxton<sup>2122</sup> used flow cytometry to observe binding of anti-lipopolysaccharide monoclonal antibodies to whole bacteria under physiologic conditions, and compared this method with whole cell ELISA and immunoblotting. Only flow cytometry could demonstrate subpopulations of cells with different binding characteristics. Eitzman, Hendrick, and Srien<sup>2148</sup> described a procedure for measuring quantitative immunofluorescence in single yeast cells, using a transfected *E. coli lacZ* gene as the test antigen.

Allman et al<sup>2142</sup> examined forward and orthogonal scatter signals, Coulter volume, and ultrastructure of *Azotobacter vinelandii* under various culture conditions and observed that forward scatter tracked Coulter volume better than did orthogonal scatter. In another paper<sup>2143</sup>, they found that the addition of DNA content, measured with mithramycin-ethidium bromide, to forward and orthogonal scatter measurements gave much better resolution of different species than did the two scatter signals. Miller and Quarles<sup>2144</sup> reported some success in bacterial identification using FITC/PI staining.

Hiraga et al<sup>2145</sup> used flow cytometry to monitor morphologic effects of plasmid genes in *E. coli*; Poulsen and Jensen<sup>2146</sup> detected morphologic effects of chromosomal genes in the same organism in the same way. Sazer and Sherwood<sup>2147</sup> stained the fission yeast *Schizosaccharomyces pombe* with Hoechst dye and chromomycin, noting the different base ratios of mitochondrial and nuclear DNA, and reported that mitochondrial growth and DNA synthesis could occur in the absence of DNA synthesis. However, Carlson et al<sup>3439</sup>

subsequently questioned whether DNA fluorescence measured from the cytoplasm was due to mitochondria.

Hécharad et al<sup>2149</sup> used flow cytometry to monitor the interaction between cocultured *Listeria monocytogenes* and an antagonistic *Leuconostoc* strain producing an anti-*Listeria* bacteriocin. Pinder et al<sup>2150</sup> examined flow cytometric counting of bacteria in suspension using forward scatter and ethidium fluorescence and found excellent correlation with plate counts. Russo-Marie et al<sup>2151</sup> applied the FACS-Gal reporter gene technique, using fluorescein galactopyranoside (pp. 408-9), to differentiating *Myxococcus xanthus* cells. Manafi and Kneifel<sup>2152</sup> provided a discussion of fluorogenic substrates in general and their applications in microbiology.

### Cell Cycles and Cell Division

Boye, Lobner-Olesen, and Skarstad and numerous others<sup>2110-26,2141,3381-2,3421-33</sup> continue to apply DNA flow cytometry to determining characteristics and control mechanisms of the **bacterial cell cycle**. Ueckert et al<sup>3434</sup> combined propidium staining for loss of cell membrane integrity and CFSE labeling to study the effects of mild heat treatment and low concentrations of nisin on division of *Lactobacillus plantarum*; they were able to discriminate as many as eight generations of daughter cells. Porro et al<sup>3435-7</sup> used DNA and protein and/or cell wall labeling to follow cohorts of daughter cells of *Saccharomyces cerevisiae*.

### Fluorescent Protein Methods in Microbes

Valdivia and Falkow<sup>3440-5</sup> and coworkers were among the first to apply flow cytometry and GFP expression in studies of bacteria and yeasts, with emphasis on analysis of genes related to bacterial virulence. Others<sup>3446-53</sup> have used GFP and other fluorescent proteins in a wide range of applications.

### Microbial Communities: Will Flow Work?

Few of us believe that eukaryotic cells can't tell the difference between life in suspension culture and life in the urban cellular environment of a multicellular organism. As we learn more about microorganisms, it is becoming more difficult to maintain the notion that even free-living autotrophs go through life uninfluenced by their peers.

Bacteria differentiate; the process, exemplified by sporulation in *Bacillus subtilis*<sup>3455</sup> and the generation of swarmer and stalked cells in *Caulobacter crescentus*, involves asymmetric cell division under the control of signal transduction proteins<sup>3456-7</sup>. Flow cytometry and fluorescent probes have been applied in studies of both phenomena just mentioned.

A variety of chemical signal molecules mediate **quorum sensing**<sup>3458-9</sup>, the process by which groups of bacteria coordinate their behavior, taking on some of the functions of multicellular organisms. Flow cytometric studies of dormancy and resuscitation in *Micrococcus luteus*<sup>2753,4</sup> aided in the discovery of resuscitation promoting factor (Rpf), a "bacterial cytokine"<sup>3460</sup> that stimulates the growth of *M. luteus* and of other high G-C Gram-positive organisms, including *Mycobacterium tuberculosis*, which make similar proteins.

Quorum sensing regulates bioluminescence, mating, sporulation, and virulence factor expression, and the formation of **biofilms**<sup>3461</sup> in a variety of bacterial species. An established biofilm comprises microbial cells and an **extracellular polymeric substance (EPS) matrix**; we can expect that flow cytometry of bacteria removed from a biofilm will omit some relevant particulars, as we have come to expect of flow cytometry of cells removed from solid tissues and tumors. If we want to analyze bacteria in biofilms *in situ*, we need only keep the same probes and switch to scanning, image, or static cytometry.

### Bad Guys Don't All Wear Black Hats: Microbial Detection/Identification in Health-Related Contexts

There are a lot of microorganisms out there; Elmer Pfefferkorn of Dartmouth, one of my daughter's microbiology professors, described the world as coated with a "fecal veneer." We and our ancestors have coexisted with a huge number of genera and species for millions of years, only learning within the past two centuries that a few among the invisible multitudes with which we share the planet are our implacable enemies, and that a few others can do us harm when they get into the wrong parts of our bodies and/or when our defenses are down.

We pay sanitary and food microbiologists, clinical microbiologists, and the microbiologists working in our macroscopic defense establishment to look for the bad guys in a large number of samples from a wide variety of sources, and a quick look at the literature tells us that most of these microbiologists are still searching for faster, cheaper, more sensitive detection methods. The cytometric strategies for detection are pretty much the same in all areas.

### The Basic Questions

Neglecting the details for the moment, the microbiology laboratory can be envisioned as a black box to which the inputs are material ("atoms" in today's information technology parlance) and from which the outputs are items of information ("bits"). The input is a solid or liquid sample; the outputs are the answers to one or more questions:

1) Is evidence of the activity of microorganisms present in the sample?

2) If so, what microorganisms?

And, for clinical and defense purposes:

3) To which antimicrobial agents, if any, are the microorganisms susceptible?

The evidence of microbial activity required for an affirmative answer to the first question might include the presence of microbial antigens or gene sequences, or the presence of host antibodies to microorganisms, or the presence of viable microorganisms; if the organisms themselves cannot be found, it may be more difficult to obtain definitive answers to the second and third questions.

Moving from the ivory tower to the real world of the laboratory, still minus the details, it is clear that somewhat different processes are in place for dealing with bacteria,

fungi, and protozoan parasites, on the one hand, and viruses, on the other. For the former, finding evidence of microbial activity almost always means eventually finding viable (i.e., culturable) organisms in the input sample; determining the identities and antimicrobial susceptibilities of these organisms typically requires the establishment of pure cultures.

Routine culture of viruses is much less common; detection is typically accomplished using PCR and other nucleic acid amplification techniques, which also allow identification and, in some cases, susceptibility testing. Clinical laboratory diagnosis of many viral infections is based on demonstration of antiviral antibodies,

There is little question that cytometry, flow and otherwise, can answer the questions listed above, and that, in at least some cases, the required information can be obtained faster by cytometric methods than by classical bulk culture-based technology. However, it is almost certain that cost-effectiveness will be the principal determinant of whether cytometry will become widely used for detection and identification of microbial pathogens.

Bacteriology laboratories haven't changed a lot during the past century; Pasteur would feel pretty much at home in a "modern" lab. The first task facing the lab when a new sample comes in is **bacterial detection**, that is, determining whether there are microorganisms, or pathogenic microorganisms, in the sample at all. In some cases, this can be done by looking at the sample under a microscope, perhaps using Gram's or another specialized staining technique, or staining with a fluorescent dye such as acridine orange and using a fluorescence microscope. This procedure is referred to as **direct detection**; it works best on samples that normally contain few or no bacteria, or samples in which the pathogens you're after can readily be distinguished from other bacteria normally present in that type of specimen.

Direct detection, however, is labor-intensive. It takes ten or fifteen minutes to take a urine sample, for which most microbiology texts recommend an initial attempt at direct detection, spin down the sediment, make a slide, and stain it. It also takes a well-trained, skilled technologist, because bacteria are near the limit of resolution of optical microscopes, and the tech has to be able to keep the scope clean and in good alignment and know how to use it. Otherwise, the whole business is a waste of time. It only takes a minute, however, for a minimally trained person to put a small aliquot of the urine specimen on a plate containing blood agar or some other nutrient-rich *cordon bleu* medium, and wait until the next day, or at least the next shift, to see if anything grows. By that time, a more trained individual is likely to be able to look at all of the plates on which there are colonies, and determine that some of them don't need to be looked at further because whatever is on them is likely to be insignificant or a contaminant.

#### Detection: Intrinsic Parameters are Not Enough

At its simplest, the flow cytometer mimics the microscope. Measurements of forward and/or orthogonal light

scattering signals provide the information a technician would obtain by visual examination of an unstained slide. An alternative cytometric measurement of size, capable of discriminating particles in the bacterial size range from larger and smaller objects is obtained from measurements of electrical (DC) impedance made using a Coulter orifice. It was shown more than twenty years ago<sup>1015</sup> that particle counting by this technique was effective in detecting clinically significant bacteriuria (the criterion in use at the time was 100,000 organisms/mL). The false negative rate for such analyses was low, i.e., bacteria, whenever present, were detectable. The false positive rate was unacceptably high, because the single-parameter electronic volume measurement could not discriminate between bacteria and other organic and inorganic particles in the same size range.

Two bacterial species differing substantially in size, shape, and/or refractive index may be distinguished by their forward and orthogonal scatter signatures, but two species chosen at random are far too likely to occupy the same region of the measurement space to make two-parameter scatter measurements alone generally useful either for distinction between species or for discrimination of microorganisms from other small particles. Fungi, which are, in general, larger than bacteria, can be distinguished from them on the basis of scatter signals, but, again, scatter signals alone may not be adequate to discriminate between fungi and other particles in a specimen.

#### Detection: Fluorescence Improves Accuracy

Improvements in cytometric detection of microorganisms typically rely on fluorescent staining; nucleic acid stains, fluorogenic substrates, and membrane potential-sensitive dyes have all been used for this purpose. These reagents all produce stronger signals, and require less sample preparation time, than would be necessary to detect organisms using labeled antibodies, lectins, or oligonucleotide probes. Although the specificity of antibodies and oligonucleotides may be useful for identifying organisms once they have been detected, it limits the utility of the reagents in the detection process unless the sample is being screened for one or a very few pathogenic species.

#### Detection: When the Tough Get Going

When you are looking very hard for one pathogenic species, e.g., *Bacillus anthracis*, flow cytometry, notwithstanding fifty plus years' work on detecting that particular bug, may go right out the window. In late 2001, after anthrax-by-mail had caused a number of fatal and near-fatal infections<sup>1467</sup>, I got a call from a *Wall Street Journal* reporter interested in why the Army didn't seem to be willing to release its flow cytometric technology to the people then screening federal offices and postal facilities for anthrax spores. I told him that it was unlikely that flow was going to get anywhere near the level of sensitivity that those screeners seemed to be achieving. At the time, I thought they were using PCR; they weren't. They would turn on a mail sorting machine and

suck air out of it for ten or twenty minutes, blowing the air over a plain old agar plate<sup>3463</sup>. Pretty low tech, but they could reliably detect a single colony of *B. anthracis* on a plate, and I doubt that any fancier method could have done better.

Similar detection problems arise under less dramatic circumstances. If you are trying to find a dozen or so colonies of *E. coli* O157:H7 on a side of beef, the only way you can hope to do it is to hose down the carcass, filter the wash water through a 0.22  $\mu\text{m}$  pore filter, and plate the filter. You might try to use appropriate antibodies and/or rRNA probes and a fluorescence microscope or a scanning cytometer of some kind, but it would be a lot easier and a lot cheaper to just incubate the plate for a few hours and then apply specific reagents.

A blood culture can turn out positive if there is one viable bacterial cell in the 10 mL of blood originally drawn. If we had a fast enough flow cytometer to run all the blood through in a reasonable time, and we wanted to make sure we had a positive culture, by counting around 50 organisms, we would have to draw and process a unit of blood from the patient. We don't do that, of course; the machines that process blood cultures detect products of bacterial metabolism in the blood, after it has been incubated for a while, and will generally not respond unless there are at least  $10^5$  metabolically active organisms/mL of medium. I noted on p. 515 that a flow cytometric technique<sup>919</sup> had detected *E. coli* seeded into human blood samples at concentrations of 10-100 organisms/mL; while cytometry is impractical for detecting that one viable cell in 10 mL without an incubation period, it should be able to provide a definitive answer after an incubation period six to ten generation times shorter than is necessary for competitive technology.

### Identification: Too Many Broths...

The next step in the process, for samples in which organisms have been detected, is **bacterial identification**. As a first step, it is traditional to look at a Gram-stained slide of the organism. What happens next depends on how many suspects there are.

In 1988, Phillips and Martin<sup>2258</sup>, who had done several studies on immunofluorescence analyses of bacteria at the U.K. Biological Defence Establishment at Porton Down, using an Ortho flow cytometer<sup>568,914,5</sup>, concluded that the low scatter sensitivity then available limited what could be done in terms of bacterial identification. Without enough of a scatter signal to trigger on, detecting the immunofluorescence signals was hopeless. Obernesser, Socransky, and Stashenko<sup>3219</sup>, doing immunofluorescence analyses on oral flora in a decidedly civilian environment, reached a similar conclusion in 1990. The conclusions of both reports might have been different had the investigators been using instruments better suited to bacterial analysis.

There is, however, a fundamental problem with focusing on the use of flow cytometry for bacterial identification, as opposed to bacterial detection, or even to sensitivity testing,

and it is this: there are too many kinds of bacteria, and the nature of flow cytometry makes it very difficult for this technology to be competitive in a situation where there are thousands of species about which you need to be concerned.

It has been more or less traditional for people involved in a project to identify bacteria by flow cytometry to start out with a few well-known organisms, and demonstrate the ability to tell them apart. A good example can be found in Figure 7-14 (p. 318), which shows separated clusters of *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa* in a two-parameter display of Hoechst 33342 and chromomycin A, fluorescence. Van Dilla et al<sup>279</sup>, in 1984, applied this dye combination, which is sensitive to DNA base composition, and which had been used to stain and sort human chromosomes, to bacterial analysis; the three organisms shown, which, respectively, contain 31%, 50%, and 67% G+C, are well separated. Further work in this area<sup>1340-1</sup> made it possible to resolve a few more species and to detect bacteriophage infection in *E. coli* by the attendant change in base composition.

This approach is fine, if you're trying to identify one of half a dozen or so organisms. If you were looking at cerebrospinal fluid from a patient with signs of bacterial meningitis, you'd know that the infection was likely to be caused by one of four or five organisms, and you could probably say that it was one of them or something else using base composition, or multiplex antibody staining with two-color immunofluorescence, or FITC/PI, or even forward and orthogonal scatter. However, if you happen to be looking at urine, or blood, both of which account for much higher percentages of the average clinical bacteriology lab's workload than does spinal fluid, even if you consider only the common pathogens found in your institution during the past year, your list is likely to have dozens or even hundreds of organisms on it.

This is most commonly done using a battery of selective media, in a 96-well plate or equivalent, each well of which is inoculated with organisms from the same colony. An intermediate step is often required, in which cells picked from a single colony on a plate are grown in broth culture to provide enough inoculum for identification. It helps to know the Gram-staining characteristics of the organism before inoculating it into selective media, because different sets of media are frequently used for Gram-positive and Gram-negative bacteria.

After another few hours, it becomes apparent which energy sources will and will not support the growth of the organism, and which chemical reactions it can and cannot perform. There are a lot of possible patterns of growth and metabolism in 96 wells, and the developers and manufacturers of bacterial identification tests have made sure that they will get different patterns for any of at least several hundred species. Well, okay. Why can't you just do the same tests by flow cytometry? You could, of course; just look at the cell growth, or the cell metabolism, or whatever, in each well, with the flow cytometer. The problem is that when you try to do that, one well at a time, even with high-throughput

flow cytometry, it may take you ten minutes or more to read one 96-well test. The conventional 96-well test is read in under a minute in a plate reader that uses 96 LED's as light sources and 96 photodiodes as detectors. Even with microfluidic flow cytometers, there's no way you'll get a system with 96 flow cells at any reasonable cost. Conventional flow cytometry for bacterial identification is only likely to be practical when you're looking for very small numbers of one or a few different organisms; you can use a gene probe or fluorescent antibody for specific identification, and scatter parameters and perhaps a nucleic acid stain to narrow down the gating region, treating the identification problem as rare event analysis (pp. 469-71).

If you happen to be looking for biological warfare agents, you've really got a problem. In the age of genetic engineering, what the other side is likely to throw at you may be an organism for which you haven't got the right fluorescent antibody or gene probe. I'll have some suggestions about what to do in this situation in a later section.

### Identification: Can Multiplexing Help?

On p. 475, I suggested several possible solutions to the multiple aliquot problem involving multiplex fluorescence. Cells in media containing different nutrients or inhibitors (for identification), or different drugs (for susceptibility testing) could be "color coded," either by embedding them in gel microdroplets containing mixtures of dyes in different proportions, or by directly labeling the cells with mixtures of tracking dyes or high-affinity nucleic acid dyes with different spectral characteristics. The direct labeling approach would probably require use of a high-sensitivity, slow-flow cytometer to detect more than four or five differently labeled populations; the gel microdroplet approach could probably be run on a commercially available instrument such as a Luminex 100.

Ye et al<sup>3464</sup> may have come up with a better idea. Their group at Glaxo Wellcome, which has been using Luminex's technology for detection of single nucleotide polymorphisms<sup>2,373-4</sup>, has adapted the same technology to bacterial identification using genus- and species-specific rRNA sequences. They report that assays can be done at a rate of almost 100/h, starting with DNA extracted from a few thousand organisms, with a cost per test of about one dollar.

We can now look at some of what has been attempted in the areas of environmental and sanitary microbiology, food microbiology, biowarfare agent detection, and clinical microbiology, remembering that hindsight is usually 20/20.

### Environmental and Sanitary Microbiology

Several groups<sup>2133-5</sup> have used flow cytometry to study growth of food-borne pathogens and agents causing fish diseases under various environmental conditions. Volsch et al<sup>2136</sup> combined propidium staining with immunofluorescence to detect two different serotypes of ammonia-oxidizing bacteria, present at concentrations of 0.1 to 2%, in activated sludge from sewage plants.

Porter et al<sup>2157</sup>, using fluorescent antibodies and sorting mixtures of *Staphylococcus aureus* and *E. coli*, found that *S. aureus*, when mixed in different proportions with *E. coli*, could be selectively recovered at a purity in excess of 90%, even when *S. aureus* composed less than 1% of the total cells. Sorting with fluorescently labeled antibodies specific for *E. coli* was also tested for the ability to recover *E. coli* from natural lake water populations and sewage; sample purities of greater than 70% were routinely achieved, as determined by colony counts. Populations of *E. coli* released into environmental samples were recovered at greater than 90% purity.

### Water That Made Milwaukee (and Sydney) Infamous

In 1993 and 1994, the drinking water supply in Milwaukee became contaminated with the protozoan parasite *Cryptosporidium parvum*, which caused many cases of diarrhea and some deaths. I noted in the previous edition that a flow cytometric technique for monitoring drinking water for this and other parasites, developed by Vesey et al<sup>2221,4</sup>, was being used in Australia, and suggested that we ought to think about it in the United States, too. "Maybe I'll stick to Foster's for a while," said I.

In 1998, while I was visiting Sydney (and being escorted by Hopi Yip, who was involved in the water analyses, to visit Duncan Veal, Belinda Ferrari, and others at Macquarie University, where the methodology was developed), the flow cytometric monitoring system detected *Cryptosporidium* in drinking water from several sources in town. Nobody seemed to know where the parasite came from; the grisly end of a dead kangaroo was one suggestion. Interestingly enough, there did not appear to be a widespread outbreak of diarrhea due to *Cryptosporidium* in Sydney at the time, although it might have been somewhat harder to detect due in the presence of another GI bug, presumably viral (I dubbed it the "Anzac two-step"), that had been making the rounds for some weeks before parasites were found in the water supply.

*Cryptosporidium* is hard to stain, and doesn't have a lot of surface antigens; the procedure used for detection in 1998 involved presumptive flow cytometric identification based on scatter signals and single-color immunofluorescence, followed by fluidic sorting onto filters, and subsequent visual examination. The Macquarie methodology for detection of both *Cryptosporidium* and *Giardia* has been improved considerably by the use of dual color immunofluorescence and immunomagnetic separation<sup>3465,70</sup>, but I am told that flow cytometry is no longer in routine use for water monitoring in Sydney, and I've gone back to American beer (Sam Adams isn't from Milwaukee, anyway).

For what it's worth, in 2001, Lindquist et al<sup>3471</sup> compared four fluorescent antibody-based methods for detection of *Cryptosporidium parvum* in surface water, and reported that solid-phase cytometry had the highest presumptive and confirmed detection rates. Although flow cytometry had the

next highest presumptive detection rate in reagent water, it placed third in analyses of spiked surface and tap waters, and, as used by these authors, lacked a confirmation procedure.

### Food Microbiology

Garcia-Armesto et al<sup>2158</sup> and Laplace-Builhe et al<sup>2159</sup> considered applications of flow cytometry to food microbiology. Flow cytometry has been used in conjunction with viability markers such as FDA for rapid counting of yeast, mold, and bacterial cells in food products using Chemunex's single-parameter flow cytometer<sup>2160</sup>; this has allowed rapid detection of low numbers of microbial contaminants. The correlation between flow cytometric results and product shelf life was excellent. Chemunex's instrument line (p. 430), now includes flow and solid phase cytometers; they have been used for fermentation monitoring as well as for detection of microbial contaminants in food and water.

I have already (pp. 430-1) mentioned that instruments for counting bacteria in milk are available from Bentley Instruments, Delta Instruments bv, and FOSS Electric A/S. Using a conventional flow cytometer with fluorescent antibodies and propidium to detect *Listeria monocytogenes* in milk, Donnelley, Baigent, and Briggs<sup>2161</sup> reported that flow cytometry yielded a 5.86% false positive rate and a 0.53% false negative rate when compared with standard culture procedures. McClelland and Pinder<sup>1422</sup> were able to detect *Salmonella typhimurium* in dairy products at levels of 10<sup>4</sup>/ml using flow cytometry and fluorescent monoclonal antibodies.

Hennes et al<sup>2335</sup> showed that bacteriophages parasitic on Cyanobacteria retained dimeric cyanine dyes such as YOYO-1 sufficiently well to be used to identify their target species in mixed populations by fluorescence microscopy. Goodridge et al<sup>13473</sup> adapted this technique for detection of *E. coli* O157:H7, using a bacteriophage shown to attack most known varieties of this strain in combination with immunomagnetic separation. They estimated that detection limits in food products could be as low as 10<sup>2</sup>-10<sup>3</sup> organisms/ml, a level of sensitivity equivalent to that obtainable using PCR.

### Bioterrorism and Bioopportunism

As I have pointed out before (p. 74), flow cytometry of biological specimens began with attempts at rapid detection of bacteriological warfare agents by Gucker et al under U.S. Army auspices in the 1940's. Various American, British, and Canadian defense agencies, and their counterparts elsewhere, have continued to provide support for, and do, significant work on flow cytometry of bacteria<sup>2423,2574-5,3474-6</sup>.

For most military applications of flow cytometry, the specimen is likely to be the output of a device that concentrates particulate matter in aerosols; in the early 1990's, the U.S. Army build several dozen mobile chemical and biological agent detection labs into Humvees, equipping each with a Coulter EPICS XL flow cytometer into which were fed samples from aerosol concentrators, stained with the acridine

dye coriphosphine O. The Army next contracted with Los Alamos and Bio-Rad to develop a smaller instrument with lower power consumption; the result was what is now sold by Apogee (to qualified buyers; otherwise they have to kill you) as the A20 (see p. 430). A parallel effort attempted to develop a detection system based on the B-D FACSCount, the notion being that several hundred of these would be mounted on top of buildings at military bases around the world. I can just see the KC-135 modified to change the sheath water.

It's gotten hard to keep track of what's going on on the military side of the biowarfare game, but business seems to be picking up in the homeland security area since the anthrax attacks. A company called PointSource Technologies, LLC (<http://www.safewater.tv>) has been getting some press recently, having received a patent on what appears to be a flow cytometric method for detecting individual bacterial pathogens in water supplies using scatter signals in sixteen different angular ranges. Their Vigilant X-3 Microbiometer was used to monitor the water supply at Qualcomm Stadium during the 2003 Super Bowl (see the Web site for details). Not that the biggies in the flow cytometry business aren't looking for a piece of the action; they're just being more discreet.

If I seem to lack enthusiasm for much of the effort that has been made of late to apply cytometry to biowarfare agent detection, it is because I think many of the decision makers involved in the process, as opposed to the people actually doing the work, have gotten overly enthusiastic about the technology and lost sight of what it can and can't do. Airborne Instruments Laboratory built a bacterial detection system for the Army in the 1960's that was essentially a static cytometer in a somewhat bulky backpack; it collected cells on a tape and stained them with an acridine dye. I suspect its performance was not much worse than that of a Humvee-based flow cytometer. I also believe that some really compact, small, inexpensive cytometric instruments could now be developed for use by the military if and when realistic specs are arrived at, and that flow may not be the best way to go.

Meanwhile, recent past and current events have occasioned some concern about whether what is published in the open literature might give aid and comfort to bioterrorists and rogue states, with a group of journal editors and other interested parties concluding that "Journals and scientific societies can play an important role in encouraging investigators to communicate results of research in ways that maximize public benefits and minimize risks of misuse."<sup>3477</sup>

### Viruses and Other Intracellular Pathogens

Direct detection of viruses by flow cytometry is relatively new, but the technology has been used for decades to detect infection of cells by viruses and other intracellular pathogens, such as chlamydia, by changes in nucleic acid content and/or by expression of pathogen-derived or pathogen-related sequences or antigens<sup>574,614,933-5,1403,2230</sup>. A report

showed that cytokine-induced expression of **human immunodeficiency virus** in a chronically infected line was accompanied by increased expression of membrane-bound IL-1 $\beta$ <sup>96</sup>; **HIV P24 antigen**<sup>2162-5</sup> and mRNA<sup>1403</sup> can also be detected in peripheral blood mononuclear cells. **Virus-cell interactions** can also be studied using membrane probes<sup>486,575</sup> or covalently labeled virus particles<sup>453,1485-6</sup>.

McSharry et al<sup>2166</sup> described a rapid method for detection of **herpes simplex virus** in clinical samples following amplification in tissue culture. Qvist et al<sup>2167-8</sup> developed a method for flow cytometric detection of bovine viral diarrhea virus in blood cells from persistently infected cattle, and found it to be at least as sensitive as virus isolation in cell culture. Others applied flow cytometry to interactions of cells with rickettsiae<sup>2169-70,2187</sup> and to analysis of antibody binding to chlamydia elementary bodies<sup>2171</sup>. McSharry reviewed the uses of flow cytometry in virology in 1994<sup>3478</sup>; more recent work will be discussed in the section on clinical microbiology.

Scatter signals from medium-sized and large viruses are detectable in laboratory-built and in some commercial flow cytometers<sup>94,688,1246</sup> (see Figure 7-5, p. 288), and we have already noted (pp. 522-4) that detectable fluorescence signals can be obtained from viruses treated with cyanine nucleic acid dyes. Autofluorescence is not a problem when measuring individual virions, so it is likely that a measurable immunofluorescence signal could be obtained from a single virion using a slow flow system and, if necessary, appropriate amplification techniques.

It is now feasible to build a flow cytometer that could characterize phenotypic and, possibly, genotypic heterogeneity in virus populations, and, when operated in an environment designed for biohazard containment, allow sorting of single virions with different characteristics for subsequent study in culture. The instrument is not likely, in itself, to be any more expensive than the fancier cell sorters now on the market; we're not talking about the superconducting supercollider. However, it seems to me that these gadgets should be installed at the CDC, NIH, and Fort Detrick, because virus sorting will, as cell sorting did, allow questions to be answered that could not be answered any other way.

### Clinical Microbiology

Álvarez-Barrientos et al<sup>3479</sup> produced an extensive and well-referenced review on applications of flow cytometry to clinical microbiology in 2000. I wrote a shorter piece, echoing much of what is said here, in 2001<sup>3480</sup>.

Clinical microbiology is regarded as an area in which flow cytometry looks very promising. It's looked very promising for a generation, and millions of dollars in venture capital have been lost on what, in retrospect, weren't outstandingly sensible approaches.

When most people contemplate the gold in the hills – or ills – of clinical microbiology, they are thinking about **diagnostic bacteriology**, on which over a billion dollars are spent annually. The detection and identification phases of diagnosis have been introduced on pp. 528-31.

The ideal clinical specimen for flow cytometric analysis is one in which relatively few particles and few bacteria are found in the absence of an infection, and in which large numbers of bacteria are found when an infection is present. Blood is hardly ideal, because there are too many large objects such as platelets and red and white cells getting in the way, and, even when the patient is suffering from overwhelming septicemia, there may be no more than 1 organism in each mL of blood (see p. 530).

While spinal fluid, even in a case of meningitis, typically contains far fewer cells than blood, and while you may only need to look for a few different kinds of bacteria or fungi in it, there are still problems; the sample volume submitted for analysis is usually much less than 1 mL, and specimens from patients with bacterial meningitis may contain only a few dozen microorganisms.

**Urine** is an excellent specimen. Between a third and half the specimens submitted for bacteriologic workup nationwide are urine specimens, so any cost-effective technology that could improve analysis in this area should find widespread application. And urine is, believe it or not, relatively clean. In uninfected individuals, urine is sterile and contains few particles; in patients with urinary tract infections, urine typically contains at least tens and, more often, hundreds of thousands of bacteria per mL. This means that urine samples could be analyzed by flow cytometry without much prior processing; there's no need for centrifugation or filtration, or for lysis of cells. In fact, if your instrument can count both the white cells and the bacteria in a urine specimen, it will do much better at diagnosing urinary tract infections.

I have already mentioned (p. 529) that a Coulter counter fitted with a small orifice can detect almost all cases of significant bacteriuria, but that it also identifies other noninfectious particles in urine as bacteria. The capacities of Sysmex's UF-50 and UF-100 flow cytometric urine analyzers (p. 510) for detection of bacteriuria have gotten mixed reviews<sup>3455-7</sup>. I don't doubt that an instrument using a suitable combination of nucleic acid stains, fluorogenic substrates such as FDA, and membrane potential probes would be able to identify bacteria in samples, determine their metabolic activity, and discriminate them from noninfectious inorganic and organic particles in the same size range.

In the previous edition, I waxed almost lyrical about the capabilities of small, red laser source flow cytometers and red-excited cyanine membrane potential dyes for bacterial detection and identification. In this edition, I have outlined an approach to a flow cytometric "Gram stain" using these instruments and reagents (pp. 516-7); last time around, I pointed out that the instrument could also identify fungi, and leukocytes (which, in urine, provide independent confirmation of the existence of bacterial infections) in the same samples used for bacterial detection. I also mentioned that, since bacteria will maintain membrane potentials in media in which they can grow, and lose membrane potential in media in which they cannot or in the presence of compounds that inhibit their metabolism, it would be possible to

do identification steps beyond the "Gram stain" using the flow cytometric membrane potential measurement. For example, metabolic inhibition by crystal violet will distinguish *Staphylococcus* from *Streptococcus* species. I am less enthusiastic about this approach now; I suspect that it makes more sense to do growth- and inhibition-based identification using scanning cytometry and "nanowell plates" containing small numbers of organisms, preferably incorporating microfluidics on-chip<sup>251,24</sup> to facilitate sample preparation, and the same approach may be in order for susceptibility testing. I am sobered by what I hear from the people I know in the diagnostic microbiology business; they tell me that all of this has to be done for a quarter, and that may be a tall order.

### Antimicrobial Susceptibility Testing: One Size Does Not Fit All

What the clinicians generally care most about is not so much detection and identification as **antimicrobial susceptibility testing**, i.e., determining which drugs kill or arrest the growth of the organism, and what concentrations of the effective agents are required. This can be initiated from the same inoculum used for the identification process, sometimes making the clinically relevant information about which drug to use available before identification of the organism has been completed.

From the 1980's on, an increasing percentage of clinical bacteriology laboratories have installed automated systems for identification and susceptibility testing, which provide results in 2 to 7 hours, rather than in 15 to 24 hours, as is the case when traditional culture methods are used. The automated systems, although originally conceived as labor- and money-saving, as well as timesaving, have turned out to increase laboratory costs. However, an older study by Doern et al<sup>225</sup> and more recent work by Barenfanger et al<sup>2481,4</sup> document the clinical impact of rapid identification and susceptibility testing; patients for whom diagnoses were made more rapidly with the aid of automated systems had significantly lower mortality rates and hospital costs and shorter hospital stays. The motivation for developing cytometric techniques for rapid susceptibility testing is stronger than ever. Now, all we have to figure out is how to do them.

In many clinical situations, e.g., in the context of managing urinary tract infections, knowing whether the pathogen is bacterial or fungal and, if bacterial, whether it is Gram-positive or Gram-negative, is usually enough to allow a physician to decide which antibiotic(s) to prescribe, at least initially. The use of existing systems for sensitivity testing would permit a prescription to be changed, if necessary, within 24 hours. Other situations, e.g., septicemia and meningitis, may require more rapid answers.

In considering responses to biological warfare, the defense agencies have traditionally thought in terms of administering antitoxins in the short run and immunizing personnel against the agent, in the longer run. It is probably more sensible to consider antimicrobial agents as the short-run de-

fense; it is poor strategy for your adversary to release an agent against which no antimicrobial is effective, and also poor strategy to use an agent against which you are likely to have stockpiled antitoxin and vaccine. Unfortunately, the major reason we now have to think about defense against biological warfare is that it has been, and may again be, used by less rational individuals than we once thought might use it<sup>3462</sup>, so all bets are off.

When I first took the position that, faced with serious bacterial infections and/or biowarfare agents, we should determine bacterial antimicrobial susceptibility first, initiate treatment, and then wait a day or two for definitive identification, it seemed to be heresy; it now appears that other people are willing to consider what I call the "Andromeda Strain" approach. The precise species and strain of the organism are of epidemiologic and/or forensic significance; getting the patient on the right drug is time-critical, and, if you don't have specific reagents for an organism, you can still figure out how to do that.

Over the years, a lot of people have considered the use of flow cytometry for **antimicrobial susceptibility testing**. There are two main classes of antimicrobial agents. **Bactericidal agents**, e.g., penicillin and streptomycin, kill bacteria; **bacteriostatic agents**, e.g., chloramphenicol, keep organisms from growing, but don't kill them. **The most obvious way in which to determine the effects of either type of drug on cultures is to compare bacterial counts over time in treated and control cultures**, and, after all these years, there doesn't seem to be a better indicator or set of indicators of antibiotic sensitivity that will work in all types of bacteria.

In early work, Cohen and Sahar<sup>2260</sup> used light scatter and ethidium fluorescence to identify and count bacteria in cultures from body fluids and exudates, and detected susceptibility to amikacin within 1 h in 12 of 13 positive specimens. Gant et al<sup>2077</sup>, using a FACScan, reported being able to discriminate between the effects of different antibiotics based on morphologic (i.e., scatter signal) changes. Raponi et al<sup>2261</sup> noted changes in *E. coli* capsular morphology in response to low doses of antibiotics.

I found years ago<sup>2075</sup> that bactericidal antibiotics take away membrane potentials; in addition, some antibiotics, such as aminoglycosides, diminish membrane potential in susceptible organisms within 5-10 min. Using scatter and membrane potential probe fluorescence measurements **and counts** from my little red laser system, I could determine antibiotic sensitivity of several common species within 60-90 min. Other investigators reported similar results in sensitivity testing with commercial flow cytometers; Bercovier et al<sup>857</sup> used rhodamine 123 as the membrane potential probe, while Ordonez and Wehman<sup>2263</sup> used DiOC<sub>2</sub>(3).

Early enthusiasm for the technique was tempered by the realization that the need for multiple aliquots greatly increases the time needed to test a single clinical sample. If you are testing ten antimicrobial agents at two concentrations, you have to look at twenty aliquots of sample plus a control.

A flow cytometric system can get susceptibility information for one sample in an hour or so, but ten minutes of the hour will be used to run the multiple aliquots through the instrument. If you have a couple of dozen broth cultures, flow will get the first one done faster than the 96-well sensitivity tester, but the 96-well apparatus will finish the lot well ahead.

Enthusiasm was tempered, but not extinguished. Work on flow cytometric susceptibility tests continued, as summarized in reviews by Alvarez-Barrientos et al.<sup>3479</sup>, Davey et al.<sup>3488</sup>, and Walberg and Steen<sup>3489</sup>.

### Bacteria: Confusion Reigns

Until recently, most reported studies on bacteria and fungi measured only a single fluorescence parameter, assessing “viability” by membrane integrity, determined using fluorogenic substrates such as FDA or dyes such as propidium and Sytox Green, or by the presence of a membrane potential, determined with cyanines, oxonols, or rhodamine 123. For what it’s worth, while the results of flow cytometric susceptibility tests of bacteria correlate with culture results, estimates of the fraction of viable bacteria by cytometry and from culture are typically different by at least a factor of five. The best correspondence I have ever seen was obtained in my lab, in studies initiated by Jared Silverman of Cubist Pharmaceuticals on the mechanism of action of the lipopeptide antibiotic daptomycin<sup>3490</sup>; viable counts estimated by ratiometric membrane potential were within a factor of two of plate counts. Not coincidentally, daptomycin’s antimicrobial action appears to be intimately related to its rapid depolarizing action on the cell membrane.

As was noted on pp. 519-22, once people started looking at multiple functional parameters<sup>2351,2610,3396-8</sup>, things became more complicated. Different antibacterial agents may have different effects on various functional parameters in different bacteria against which they are effective, meaning that no single functional parameter is optimal for susceptibility determination for all drugs and all species.

**Counts** still work. In most cases, one can get adequate counts of organisms in 96-well plates by determining turbidity (which is affected by the size as well as the number of organisms<sup>3488</sup>), or by using nucleic acid stains such as Pico green or tetrazolium dyes, and a flow cytometer is an expensive alternative. The “nanowell plate” approach I suggested on p. 534 may make for shorter incubation times than are needed using 96-well plates.

If one considers the plate count to be a “gold standard” for susceptibility testing and other viability determinations, it is important to remember that what is counted on a plate are colonies, and that a **colony forming unit (CFU) may be a single organism or an aggregate**. When nucleic acid stains or indicators of metabolism are used for the readout of a microwell assay, the signal is proportional to the number of organisms, not to the number of aggregates. If nothing is done to break up aggregates, the “events” detected by flow cytometry (and those sorted into plates, as illustrated in Fig-

ure 10-30, p. 521) may represent single cells or aggregates, and, if an appropriate cytometric indicator of “viability” is selected, flow cytometric data should agree well with plate counts, as was the case in our daptomycin studies<sup>3490</sup>. These were done primarily with *Staphylococcus aureus*, which forms clumps of cells. Other organisms, such as *Streptococcus pyogenes*, form long chains; disaggregation may be necessary before flow cytometry can be done. Mild sonication is the preferred technique<sup>2610,3518</sup>.

The molecular biologists would like to do away with growing bacteria altogether, relying on detection of resistance genes in amplified DNA. Flow cytometry could play a part in that if multiplexed bead assays are used for the read-out<sup>3464</sup>, or if slow flow is used to read “fingerprints” of strains with known resistance characteristics based on DNA fragment size in digests<sup>3018-20</sup>.

I still believe that multiparameter flow cytometry can play an important role in analyses of the bases of antibiotic resistance and in the development of new antimicrobial agents (p. 522). This has taken on a new urgency with the emergence of drug-resistant strains of organisms causing tuberculosis and pneumonia, among other diseases, and with increasing concern about bioterrorism. Flow cytometry can provide both direct and indirect measures of drug uptake by microorganisms, facilitating understanding of the permeability barriers and efflux mechanisms involved in drug resistance<sup>3548-9</sup>. This work will require running a lot of samples, and a lot of hazardous samples, at that.

### Mycobacteria: Down for the Count

Speaking of hazardous samples, *Mycobacterium tuberculosis* is high on my list of organisms to avoid. A single individual working at Maine’s Bath Iron Works managed to infect over 400 contacts with a fairly nasty strain of TB, and the bug is readily spread by coughing, sneezing, etc., unlike, say, HIV or Ebola virus.

While tuberculosis is a bad disease, the organism itself grows slowly enough *in vitro* so that it takes weeks to determine whether a culture is positive. This makes conventional susceptibility testing take a long time. Ronald Schell and his coworkers at the Wisconsin State Laboratory of Hygiene have developed several flow cytometric assays for antimicrobial susceptibility in mycobacteria<sup>3491-4</sup>. They initially<sup>3491</sup> used FDA as an indicator; this made it necessary to stain organisms, which is more of a problem in mycobacteria than in most other species, and to work with unfixed specimens, which scared most potential users off. However, they subsequently established<sup>3494</sup> that organisms in fixed specimens could be identified and counted based on their scatter characteristics, enabling the test to be done safely in most laboratories. Results are available in 72 hours, which classifies as rapid in this context.

### Antifungal Susceptibility: Flow Does the Job

Previously, Green et al.<sup>2262</sup> used scatter and propidium fluorescence to determine susceptibility of *Candida albicans*

and other fungi to a variety of agents within 3 h. Much subsequent work on flow cytometric antifungal susceptibility tests has relied primarily on dye exclusion tests using propidium<sup>3495-7</sup>; other studies<sup>3498-500</sup> utilize Molecular Probes' dye FUN-1<sup>2332</sup>, which localizes in vacuoles and imparts red fluorescence to metabolically active cells with intact membranes, while cells with damaged membranes exhibit diffuse yellow-green fluorescence. Acridine orange<sup>3501</sup> and membrane potential dyes<sup>3502-3</sup> have also been used as viability indicators. Perhaps because many antifungal agents act primarily on the cytoplasmic membrane, results of flow cytometric antifungal susceptibility tests of *Aspergillus* and *Candida* species and of *Cryptococcus neoformans* and *Torulopsis glabrata* correlate well with both the NCCLS M-27 standard method<sup>3497,3499-500,3502</sup> and with clinical outcomes<sup>3499</sup>; results are available several days earlier using flow.

### Antiviral Susceptibility by Flow Cytometry

Changes in the fraction of cells synthesizing viral antigens and in the patterns of expression of viral antigens have been used as the basis for tests of susceptibility of herpes simplex virus type 1<sup>3504</sup>, cytomegalovirus<sup>3505-7</sup>, and human herpesvirus 6<sup>3508</sup> to a variety of antiviral drugs; the flow cytometric assays are substantially less labor-intensive than conventional alternative methods.

From my point of view, if flow cytometry can make it anywhere in clinical microbiology, it will be in the area of bacterial detection, using inexpensive instruments and nucleic acid and/or membrane potential dyes. The technology is particularly well suited to urine microbiology, but the same machine that can work on urine can also handle cultures in liquid media. I've been saying all this for twenty years, and not much has happened. There are at least 10,000 potential sites in the U.S. in which such instruments could be placed, which represents a nice market; when you consider that there's a chance the instrument could be made inexpensive enough to put in a doctor's office, the market is even more attractive.

Or should be. BD has had a big share of the flow cytometry market and an even bigger share of the diagnostic microbiology market for decades, and never produced a flow-based microbiology product. They have invited me to pitch one to them on two occasions fifteen years apart; no sale. There are some smaller companies pursuing environmental and food microbiology (see Chapter 8), but it will probably take a big one to make a dent in the clinical area.

### Cytometry in Vaccine Development

The earlier section on lymphocyte activation documented the present ability of flow cytometry to detect antigen-specific T lymphocytes and to determine their functional capacities. Prevention via immunization remains one of the best ways of dealing with infectious diseases, and active efforts are underway to develop and refine vaccines for relatively new agents, such as HIV, and for the granddaddy

of them all, smallpox, extinct in the wild but still putting the terror in bioterrorism.

Using intracellular cytokine production as an indicator of CD8+ T lymphocyte response, Frelinger and Garba<sup>3519</sup> stimulated lymphocytes from unvaccinated and previously vaccinated individuals; while the levels of response diminished with time since vaccination, even those patients vaccinated more than 35 years prior to challenge showed some response.

Letvin et al<sup>3509</sup> discuss the prospects for developing HIV vaccines; their work to date with animal models indicates that vaccines can elicit protective antigen-specific cytotoxic T cells<sup>3510</sup>, but also that a single nucleotide mutation in the virus can result in the death of an immunized animal<sup>3511</sup>. This outcome notwithstanding, papers by the Letvin group provide an excellent example of how to assess immune responses to vaccines.

Reed et al<sup>3512</sup> developed a flow cytometric bead assay for measuring the antibody response to the "protective" antigen of *Bacillus anthracis*; multiplexed immunoassays may facilitate demonstration of antibodies to multiple antigens from multiple pathogens, whether induced by prophylactic immunization or by infection<sup>3513</sup>. Cirino et al<sup>3514</sup> developed a flow cytometric assay to identify scFv antibody fragments that disrupted anthrax toxin binding, which are potentially useful in the treatment of the infection.

Geoffroy et al<sup>3449</sup> used GFP to enable monitoring of lactic acid bacteria used as live oral vaccine vectors, while Haidinger et al<sup>3450</sup> used GFP to facilitate removal of live bacteria from vaccines made from bacterial ghosts.

### Microbiology Odds and Ends

Fouchet et al<sup>2264</sup> reviewed flow cytometric applications in the broad area of microbiology before the previous edition of this book was published. Some other older references<sup>2265-7</sup> show that dental researchers jumped on the flow microbiology bandwagon ahead of most of the rest of us. Then, there are some older and newer papers on opsonizing antibodies<sup>2268-72</sup> and bacterial interactions with cells<sup>2273-4,3514</sup>, including a few on my old friend *Helicobacter pylori* (yes, I've run some through my machine).

I still heartily recommend two excellent papers<sup>2275-6</sup> which together combine quantitative immunofluorescence, image analysis, and flow cytometry in direct demonstrations of anaerobic bacteria in stool. The subject matter may stink, but the methodology is superb. I might add that, thanks to papers like these and the work shown in Figure 10-27 (p. 518)<sup>3395</sup>, it is no longer technically correct to look at bad immunophenotyping (Figure 10-2, p. 447) and say "This looks like crap"; we now know what crap looks like.

### Parasitology

As long as flow cytometry remains an expensive technology, it is unlikely to find much use in clinical diagnosis of parasitic diseases, whatever its utility in research in this field.

There are probably nearly a billion people with malaria; most of them are poor and don't live in the United States, which has kept interest in malaria in this country focused on being able to treat the disease in American military personnel sent elsewhere.

By the time the previous edition of this book was written, flow cytometry had been used by several groups of investigators to demonstrate the presence in red blood cells of **intracellular parasites**, including various species of *Babesia* (babesiosis), *Plasmodium* (malaria), and *Trypanosoma* (African sleeping sickness and Chagas' disease)<sup>290,577-81</sup>, and to study the cell cycle of the malaria parasite *Plasmodium falciparum*<sup>93,8</sup>. DNA fluorochromes had been shown to permit discrimination of parasitized from uninfected cells and, in some cases, purification of viable infected cells by sorting. Cells containing some parasites also could be identified by their higher apparent membrane potentials<sup>290-1,939</sup>. Jackson et al<sup>940</sup> applied fluorescence microscopy with an FDA/ethidium stain to determining "viability," i.e. membrane integrity, of intra- and extracellular *Leishmania*; the flow cytometric version of this assay has since been used with numerous species of parasites.

Flow cytometry can detect malaria parasitemia, using fluorescent dyes<sup>2172-4</sup>, a cytochemical (Technicon H-1) hematology analyzer<sup>2175</sup>, and polarized scatter measurements<sup>2536-7</sup> (p. 279). It has also been used to characterize the DNA content and growth kinetics<sup>2176-9</sup> of *Plasmodium* species and their effects on red cell antigens<sup>2180-3</sup>, and to analyze the effects of drugs and other treatments<sup>1557,1619,2184-6</sup>.

Flow cytometry was also used to study the DNA content<sup>2188-92</sup>, growth<sup>2193-7</sup>, surface characteristics<sup>1481,2198-202,2214</sup>, and effects on the host<sup>2203-5</sup> of, and the effects of drugs on<sup>1579,80,2206</sup>, various species of *Trypanosoma*. Growth, surface antigens, and host cell interactions of *Leishmania* species were also investigated<sup>1421,2207-13</sup>.

Moving on to organisms which, at least occasionally, worry Americans, there was some flow cytometry done on intestinal parasites of the genera *Giardia*<sup>2215,21,2224</sup> and *Cryptosporidium*<sup>2222-4</sup>. Alderete and coworkers<sup>2225-8</sup> investigated the surface antigens of *Trichomonas vaginalis* and their relationship to infectivity; it appears that virulence of this organism is mediated by infection with a double-stranded RNA virus. Humphreys, Allman, and Lloyd<sup>2229</sup> used FDA/PI and an oxonol membrane potential dye in viability tests for *T. vaginalis*. *Pneumocystis carinii*, the causative organism of the pneumonia fatal to many people with HIV infection, also came under flow cytometric scrutiny<sup>1420,2231-4</sup>.

There were a bunch of other papers on flow cytometry in parasitology<sup>2235-49</sup> that I included in the references to the Third Edition; at that point, I declined to "open that can of worms and protozoa." I will again beg off on a detailed discussion, and point you to some more recent references dealing with *Acanthamoeba*<sup>3520-1</sup>, *Babesia*<sup>3522</sup>, *Cryptosporidium*<sup>3523-6</sup> (also see p. 528), *Eimeria*<sup>3527</sup>, *Encephalitozoon*<sup>3528-9</sup>, *Giardia*<sup>3530-1</sup>, *Leishmania*<sup>3532-6</sup>, *Theileria*<sup>3537</sup>, and *Trypanosoma*<sup>3538</sup> species.

Work on the biology and chemotherapy of malaria has continued<sup>3539-45</sup>, and some progress seems to have been made toward development of a preventive vaccine<sup>3546-7</sup>.

The first papers on detection of malaria parasitemia used the UV-excited Hoechst dyes and relatively large instruments<sup>578-9</sup>; Makler et al<sup>771</sup> took a step in the right direction by demonstrating that thiazole orange and the FACScan could be used to detect and analyze *Plasmodium* species in blood, and other recent papers used ethidium and propidium. That still keeps things in the realm of instruments that use blue-green or green excitation. However, I (unpublished) have managed to detect *P. falciparum* in parasitized red cells using oxazine 750 and a Cytomutt with a 7 mW red He-Ne laser, and this dye and others could be used in an inexpensive cytometer with a red diode laser as a light source<sup>2447</sup>. I don't know whether the billion victims are going to be any better off if such an instrument exists, but one can be made if it's needed. It can also be used for malaria research, for which funding doesn't seem to be lavish anywhere.

Meanwhile, you might want to run a copy of this section by the parasitologists and/or tropical medicine specialists in your institution, especially if they don't use your machine. Take them to lunch. Buy them acceptable beverages. You might gain friends and/or paying customers.

## Pharmacology and Toxicology

Flow cytometric analysis of drug effects on cells *in vitro* has, for some time, been considered as an alternative to animal testing<sup>2026</sup>.

### Drugs and the Life and Death of Cells

Since some of the first users of fluorescence flow cytometry were involved in cancer diagnosis, research, and treatment, it is not surprising that much early work in both the United States and Europe used **DNA content analysis** to determine **effects of anticancer drugs on the cell cycle**. In the early 1970's, it seemed there was an unending litany of papers entitled "Effects of (your drug here) on cell cycle traverse in (your cell type)"; while, from today's point of view, few of those papers seem all that informative, flow cytometry has become steadily more valuable in the analysis of interactions between drugs and cells. Testing has grown more specific; where once one might have simply followed DNA content distributions over time to detect DNA damage, there are now, for example, tests based on dual-parameter DNA/protein<sup>953</sup> or DNA/RNA<sup>954</sup> analysis, or on detection of DNA denaturation<sup>955,6</sup>. Recent discussions of drugs and the cell cycle have been published by Shackney and Shankey<sup>3550</sup> and Traganos et al<sup>3551</sup>.

In many cases, it is possible to study **drug uptake** directly, using fluorescent drugs such as the anthracyclines<sup>352,3,814-8</sup> or labeled analogs such as fluoresceinated derivatives of methotrexate<sup>354,7</sup>; this has been discussed on pp. 376-7. Charcosset et al<sup>623</sup> used flow cytometry to demonstrate that the uptake of a cationic drug, was as expected, dependent upon membrane potential; the particular drug studied

was the fluorescent DNA intercalator *N*-methylleptincium, which has been studied as an anticancer agent.

Even when direct assessment of drug uptake on a cell-by-cell basis is not possible, flow cytometry can readily provide quantitative analyses of the **effects of different drug doses on cells' metabolism** over time courses ranging from seconds to weeks, using the full range of parameters available.

The results of flow cytometric assays of drug effects on mammalian cell viability have not always correlated well with results obtained from culture. Poot et al<sup>3552</sup> report that culture of cells prior to drug treatment followed by assessment of proliferative survival by Hoechst 33342/ethidium detection of BrUdR incorporation after 72 h exposure to the label yields cytometric results comparable to those obtained from colony-forming assays.

In recent years, it has become appreciated that many cytotoxic drugs induce **apoptosis** in susceptible cells; Darzynkiewicz and his coworkers<sup>3553-5</sup> have described both drug effects and the methods for their study using both flow cytometry and laser scanning cytometry.

There is also interest in replacing established methods in **toxicology** by faster, more automated, flow cytometric methods. Zucker et al<sup>2058-9</sup> studied membrane effects of tributyltin, which were analyzed by both biochemical and flow cytometric assays. Yurkow et al<sup>3556-7</sup> used a specific antibody to monitor cellular levels of the protein of metallothionein, which increase following exposure to heavy metals. Effects of toxic agents on **spermatogenesis** can also be detected by flow cytometry<sup>2060-2</sup>.

### Erythrocyte Micronucleus Assays

Several flow cytometric adaptations have been described for the **bone marrow and blood erythrocyte micronucleus assays**<sup>2063-8,3558-68</sup>. These are standard tests for effects of **clastogenic agents**. It was noted on p. 453 that DNA damage due to such compounds or to radiation could be detected by increases in the CV of DNA histograms, but this requires carefully controlled, high-resolution flow cytometry<sup>2941-2,3569</sup>. While the nuclei of mammalian erythrocytes are normally extruded during maturation, cells exposed to clastogenic agents retain chromosome fragments, or micronuclei, which can be detected by appropriate staining.

Since the objective is to detect DNA-containing micronuclei in relatively immature red cells (reticulocytes), which normally contain RNA, it is necessary to discriminate between the two types of nucleic acid. The earlier versions of flow cytometric micronucleus assays used Hoechst 33342 or DAPI as DNA selective stains<sup>2063-5</sup>, identifying reticulocytes by thiazole orange staining, and therefore required dual-laser flow cytometers with UV and 488 nm excitation, making it impractical to implement the assays on most fluorescence flow cytometers.

Beginning in the early 1990's, Torous and her colleagues<sup>2066-8,3561-8</sup> worked toward a robust micronucleus assay that can now be run on a single (488 nm)-laser flow cytometer. Reticulocytes are identified by staining with fluorescein-

labeled anti-CD71 antibody; cells are fixed and stained with propidium after RNase treatment, and malaria-parasitized erythrocytes are used as a DNA standard<sup>3565</sup>. This test proved to be reproducible in a multilaboratory study<sup>3567</sup>. A further improvement has been reported<sup>3568</sup> in which SYBR Green or SYTOX Green replaces propidium as the DNA stain and PE-labeled antibodies are used to detect CD71; a PE-Cy5 anti-glycophorin antibody is added to improve discrimination of erythroid cells.

Micronucleus assays for laser scanning cytometers have been described by Styles et al<sup>3570</sup> and Smolewski et al<sup>3571</sup>.

### Toxic Waste and B cell Proliferation

During the 1980's and early 1990's, the Centers for Disease Control determined peripheral blood lymphocyte immunophenotypes of approximately 900 individuals living near toxic waste cleanup (Superfund) sites and 600 controls; and discovered what appeared to be a higher incidence of B cell monoclonal lymphocytosis<sup>3580</sup> (BCML), which may or may not be a precursor of B cell chronic lymphocytic leukemia<sup>3581</sup>, in the group near Superfund sites. A follow-up investigation confirmed the findings<sup>3582</sup>. The difference in incidence of BCML between the two populations was small enough so that it would not have been noticed in a study of fewer than 100 individuals; this should remind us that looking for small effects in small groups can be a (nontoxic) waste of time and money.

### Radiation Dosimetry

Snopov et al<sup>3572</sup> used an antibody against thymine dimers to estimate the dose of radiation received by mononuclear leukocytes in irradiated blood. An older technique for estimating radiation dose from the frequency of mutations at the erythrocyte glycophorin A locus<sup>3573-5</sup> has been used to study survivors of the atomic bombing of Japan<sup>3576-7</sup> and the nuclear accident at Chernobyl<sup>3578-9</sup>.

### Food Science

#### Somatic Cell Counts in Milk

**Counts of somatic (nucleated) cells in milk** serve as the principal criterion for determining whether a cow's udder is healthy and, therefore, whether its milk is suitable for consumption. In most countries, such analyses are required by law; if the presence of mastitis is indicated by an elevated cell count, the milk cannot be sold.

The major problem in somatic cell counting in milk is discrimination of cells from fat droplets; Breer et al<sup>3580</sup> showed that this could be done by adding acridine orange to a milk sample and analyzing the sample on a flow cytometer. A respectable number of Partec's smaller flow cytometers were sold to dairy concerns for somatic cell counting. When I first heard about this, it seemed to me that a flow cytometer was a bit pricey for this application; I was wrong. As it happens, the instruments then most widely used for somatic cell counting cost at least as much as flow cytometers. They

were the **Fossomatic** series, manufactured by **Foss Electric A/S** (p. 431). In these instruments, a milk sample was diluted in buffer containing ethidium bromide, which stained nuclei; the suspension was then applied to a rotating disc, forming a thin layer of cells which passed under the objective of a fluorescence microscope with a PMT, fitted with an appropriate emission filter, placed in its image plane. Foss's newer Fossomatic 5000 instruments, and their competitors from **Bentley Instruments** in the U.S. (p. 430) and **Delta Instruments** in the Netherlands (p. 431), are flow cytometers. They are not intended to get 1 percent CV's on ethidium bromide fluorescence; all they have to do is discriminate stained nuclei from other stuff in the sample; and they work well enough so that there are hundreds in use.

Ostenson<sup>2022</sup> used a more conventional flow cytometer to follow total and differential leukocyte counts in blood and milk in experimental endotoxin-induced bovine mastitis, and Saad and Astrom<sup>2023</sup> examined estrogen effects on blood and milk leukocytes. Redelman et al<sup>2024</sup>, using carboxydimethylfluorescein diacetate to label intact cells in milk, could identify five or more cell clusters on two-parameter displays of fluorescence vs. orthogonal scatter. Pillai et al<sup>3583</sup> and Rivas et al<sup>3584</sup> report that differential count information provides somewhat more information about udder health status than simple somatic cell counts; D'Haese et al<sup>3585</sup> examined a solid phase cytometer as an option for somatic cell counting and found it less effective than a Fossomatic instrument.

Bentley, Delta, and Foss also manufacture flow cytometric apparatus for counting bacteria in raw milk; this testing is, as far as I know, currently not mandatory in the U.S.

Seo et al<sup>3586</sup> reported that a rapid method combining flow cytometry and immunomagnetic bead separation followed by 6 h enrichment in culture could detect very small numbers of *E. coli* O157:H7 inoculated into raw milk, ground beef, and apple juice samples; as few as four organisms/g of ground beef could be found; Goodridge et al<sup>473</sup> estimate detection sensitivity of 10<sup>2</sup> organisms for ml in milk using their flow cytometric bacteriophage assay.

### Brewhaha

Jespersen, Lassen, and Jakobsen<sup>2025</sup> applied flow cytometry to detect wild yeast infections in breweries. After selective enrichment in culture for 48-72 h and staining with a fluorogenic substrate, they could find one wild yeast cell per 10<sup>6</sup> culture yeast cells. They probably used logarithmic amplifiers.

### A Loaf of Bread, a Jug of Wine...

Attfield et al<sup>3587</sup> showed that flow cytometry with oxonol dyes and propidium was useful for estimating the activity of reconstituted dry yeasts, which are widely used in both bread baking and winemaking. If your sourdough starter is a non-starter, check it out in your lab.

Malacrino et al<sup>3588</sup> found flow cytometry useful for monitoring populations of both yeast and the bacterium *Oenococcus*

*oeni*, which improves taste by converting malic acid to lactic acid, in wine; Graca da Silveira et al<sup>3589</sup> used flow cytometry to monitor membrane integrity of *O. oeni*.

Resveratrol, a polyphenolic antioxidant found in red wine<sup>3590-7</sup>, is reported to inhibit cell growth, including tumor cell growth, induce apoptosis in cultured leukemia cells, and, at high levels, decrease cell responses associated with inflammation. To your health!

Since cheese goes so well with wine, this is a good place to mention that Bunthof et al<sup>3598</sup> used Molecular Probes LIVE/DEAD BacLight kit<sup>2332</sup> with fluorescence and confocal microscopy and flow cytometry to monitor permeabilization of cheese starter bacteria.

### Seeing the Blight

*Phytophthora infestans*, an important plant pathogen originally classified as a lower fungus but now thought to be closer to algae and diatoms, caused the great potato famine in Ireland in the mid-19th century; other species of the same genus cause root rot in squashes, cucumbers, peppers, and other species. Day et al<sup>3599</sup> report that Calcofluor White staining, flow cytometry and a sophisticated data analysis algorithm allow *Phytophthora infestans* sporangia to be discriminated from other airborne biological particles. We don't want fries with that.

### Major Food Group: Chocolate

Last but not least in the food section, I come to a major reason I have kept such sanity as I have while generating this volume. According to Rein et al<sup>3600-1</sup>, cocoa polyphenols inhibit platelet activation *in vitro*, with the effect also being detected after cocoa consumption. Time for a chocolate break.

### Biotechniques and Biotechnology

This section is oriented toward industrial uses of flow cytometry, but includes a few tricks that didn't seem to fall under other headings I had. If you're interested, you might want to look at a 1996 book edited by Al-Rubeai and Emery, *Flow Cytometry Applications in Cell Culture*<sup>2400</sup>; a new book on *Flow Cytometry in Biotechnology*, edited by Larry Sklar, should be published by Oxford University Press in 2003 or 2004. There is a 2001 review article by Rieseberg et al on "Flow cytometry in biotechnology"<sup>3602</sup>, but it has a lot of introductory material on flow cytometry and little detail on the applications.

In the 1970's, when people first got the notion that flow cytometry might be useful in the design and analysis of industrial processes involving prokaryotic and eukaryotic cells, the metabolic reactions involved were those that had evolved with the cells; today, the influence of recombinant DNA technology is pervasive. James Bailey<sup>3603</sup>, who published some of the earliest papers on multiparameter flow cytometry of bacteria<sup>553,558</sup>, was perhaps the first chemical engineer to appreciate what genetic manipulation could accomplish in the field he called "metabolic engineering," and combined

flow cytometry and other experimental techniques with mathematical modeling to study the dynamics of bacterial and yeast populations. His students have continued to use flow cytometry for such applications as on-line monitoring of bioreactors<sup>3604</sup> and selection of yeast cells<sup>3605</sup> expressing antibodies with higher affinities than can be generated in the immune system<sup>3606</sup>.

There seem to be only a few basic approaches to flow cytometry in biotechnology. Flow cytometers without sorting capability are used for **high throughput screening**, the objective being to look at a relatively simple interaction, such as ligand binding, in a maximum number of samples in a minimum time. Fast sample handling hardware (p. 365-6) has reduced the time needed to process a single sample to *under two seconds*; multiplexing may allow samples to be mixed before analysis, further increasing throughput.

Sorters, preferably high-speed sorters, are used to isolate the “best and the brightest” fraction of a percent of cells or beads from highly heterogeneous mixed populations, based on ligand binding and/or metabolic activity.

While the applications just mentioned typically do not require measurement of a large number of parameters, it is likely that successful on-line process monitoring will, although, once the right measurement parameters have been selected, it should be possible to get by with a lower analysis rate. A number of papers relevant to theoretical and practical aspects of process monitoring, dealing with bacteria, yeast, and eukaryotic cells, have appeared since the previous edition was published<sup>3384,3396,3604,3607,20</sup>.

### Protein and Gene Expression on Cells and Beads

While phage display (p. 348) provided the first widely used technology for generating and expressing combinatorial libraries of antibodies and other proteins, the more recent trend has been toward expression of engineered enzymes, antibodies, and receptors in bacteria and yeast<sup>3621-32</sup>. The antibodies, in particular, are expected to be useful in therapy as well as in diagnosis and research. Cell sorting seems to be the preferred mode for selection in this business, but simpler technologies have been reported to work<sup>3606,3633,4</sup>.

Sydney Brenner and his colleagues<sup>2328,9</sup> have used sorting to identify differentially expressed genes by two-color analysis of oligonucleotide-bearing beads.

### Getting Big Molecules into Small Cells

There are several ways of getting large molecules such as dextrans, proteins and DNA, or impermeant molecules, such as acid dyes, into cells; Lee et al<sup>2051</sup> used flow cytometry to evaluate three. The first was **cell fusion**, in this case, with red blood cell ghosts loaded with a fluorescent reporter molecule. The second technique, **osmotic lysis of pinosomes**, involved a brief exposure of cells to a hypertonic solution containing the reporter molecule; subsequently, a hypotonic media was added which lysed the pinosomes formed during hypertonic treatment. The third technique was **scrape loading**, which creates transient holes in the cell

membrane, allowing reporter molecules to enter cells, by application of mechanical force. Osmotic lysis of pinosomes offers several advantages; it is simple, efficient (virtually all cells became fluorescently labeled), and enables larger amounts of material to be loaded more uniformly into cells while maintaining excellent viability.

**Electroporation**, in which pores in the membrane are transiently created by brief application of a strong electric field, is another widely used method for loading cells<sup>1,233,4,2052,5</sup>. Weaver et al<sup>2052,4,3645,7</sup> have used flow cytometry and fluorescence microscopy with fluorescent reporter molecules of various sizes to analyze the dynamics of the electroporation process itself and the changes which occur in membrane transport characteristics.

### Staying Alive, Staying Alive

Rodriguez and Lodish<sup>3638</sup> improved survival of attached cells following selection for gene expression and sorting into microwell plates by providing a drug-sensitive feeder layer of cells in each well which could be disposed of once sufficient growth of the sorted cells had taken place.

Katsuragi et al<sup>3639</sup> were searching for bacteria with high thiamine production, but the only assay to which they had access killed many of the bacteria. They were able to recover and culture high-producing strains by establishing colonies in microdroplets before performing the assay, since a small fraction of cells in the sorted microdroplets survived the procedure.

Zengler et al<sup>3640</sup> utilized the gel microdrop technique to culture and isolate “unculturable” bacteria from seawater and soil that require low nutrient concentrations to grow and would otherwise be overgrown by other organisms in the sample; their overall objective is identification of new sources of microbial metabolites.

### Et Cetera

Kavanagh et al<sup>365</sup> developed flow cytometric assays to quantify **cell-to-cell communication** to facilitate studies of alterations in this process induced by tumor promoters. Cells are scrape-loaded with Lucifer yellow with or without rhodamine-labeled dextran; transfer of dye(s) between donor and recipient cells can be assessed by one- and two-color fluorescence flow cytometry.

Wilson, Mulligan, and Raison<sup>2057</sup> described an assay technique for antibodies to membrane-associated antigens using polyacrylamide microspheres coupled with cell (or organelle) membranes, which provide an easily stored, standardized antigen source usable in subsequent flow cytometric assays.

Nardelli, McHugh, and Mage<sup>2069</sup> developed a soluble macromolecular conjugation reagent, polyacrylamide-streptavidin (PASA), for the simplified preparation of multivalent protein-protein conjugates. Soluble linear polyacrylamide, with a molecular weight of approximately 10<sup>6</sup>, is activated with carbodiimide and conjugated to approximately 20 streptavidin residues per molecule. PASA can bind bioti-

nylated proteins to produce homo- or heteroconjugates of known composition; it was used to prepare multivalent antibody conjugates that could bind either of two antigenically distinct cell lines. The technique is also potentially useful for making immunotoxins, tumor labeling conjugates, and complex immunogens.

Vlieger et al<sup>2070</sup> described a flow cytometric assay for **quantitative analysis of polymerase chain reaction (PCR) products**. Magnetic beads coated with streptavidin are used to capture biotinylated PCR fragments, and analyzed by flow cytometry after hybridization with a hapten-labeled probe or by immunoenzymatic reactions. The method can detect fractions of femtomoles of product. An image analysis method using chemiluminescence was also described.

### Alternatives: Microfluidic Cytometers, Flow and Static

In the early 1980's, I got the notion that it might be possible to build a "flow cytometer on a chip," incorporating integrated optics, fluidics, and electronics, and, with help from Mike Hercher, got as far as building a cytometer which used fiber optics (without lenses) for illumination and light collection<sup>877</sup>.

My original inspiration was a gadget built by Jonathan Briggs et al<sup>878</sup>, then at Syva Corporation. Their simple cytometer was essentially an epiilluminated system in which light from a He-Cd laser is coupled into an optical fiber with a 50  $\mu\text{m}$  core. The fiber is dipped into a suspension of cells, or beads. The beam diverges from the end of the fiber, at an angle dictated by the N.A. of the fiber (pp. 157-8), resulting in the intensity falling off sharply with distance from the end of the fiber. The N.A. also limits the angle at which the fiber can collect light; the closer a particle emitting fluorescence is to the end of the fiber, the more light is collected. These two effects combine to limit the region in which substantial fluorescence can be excited in, and detected from, particles in the suspension to a volume within 50  $\mu\text{m}$  or so of the tip of the fiber. When the solution is stirred, every time a fluorescent cell or bead passes through this volume, a fluorescence pulse can be detected, using a dichroic at the other end of the fiber to separate the excitation and emission wavelengths and appropriate optics to divert the emission signal to a PMT. Because of variability in signal intensities from particles at different distances from the fiber, the CV's were fairly large, around 8%; the single-fiber system also couldn't measure scatter. However, by bundling three fibers together, putting excitation down the middle fiber and collecting from the two outside, it is possible to restrict signal processing to events in which the two detector fibers produce almost equal signals, which reduces the CV. Since fibers can carry light over distances of miles without substantial losses, it would, for example, be feasible to keep the laser, PMT, electronics, etc., comfortably housed on shipboard, and (almost) deep six the business end of a fiber cytometer. Rob Olson was talking about building such a gadget, but he apparently went straight to a submersible cytometer.

Just before the previous edition was published, flow cytometry on a chip, if not on a ship, was resuscitated by Dan Sobek, Martha Gray, and Steve Senturia<sup>2309</sup>, of MIT, who described experiments with a sheath flow system microfabricated in fused silica. Luckily, they didn't try to build in integrated optics; it has since become apparent that microfluidic cytometers work a lot better with conventional optics (see p. 158).

A newer generation of microfluidic flow cytometers have been built in plastic. **Agilent's** commercial instrument (pp. 429-30) appears to incorporate molded parts. **Micronics** builds their cytometers by gluing layers of plastic together, while the Quake group at Caltech<sup>7326-7,2509,2512-4</sup> (and its commercial offshoot, **Fluidigm**), Whitesides et al at Harvard<sup>2511</sup>, and Takayama et al at the University of Michigan<sup>252-5</sup> mold systems from silicone elastomers. Microfluidic cytometers are small, and can be inexpensive; they are not fast.

On the plus side, the Quake/Fluidigm systems can incorporate hundreds of pumps and valves on a single chip, and control them with no more than a few dozen inputs<sup>2514</sup>. Flow can be stopped and reversed. These devices might better be thought of as "intelligent microtiter (or nanotiter) plates" than as flow cytometers. They are not suited for high throughput screening, but, if cells selected in a high throughput screening process are sorted into a microfluidic chip, they can be grown on the chip, subjected to repeated perturbation and "high content" analysis using imaging, confocal, or laser scanning microscopy. While microfluidic sorting is slow, it doesn't generate aerosols, and may be the best way to deal with hazardous bacteria and viruses.

I don't know about cheap confocal microscopy, but the small, inexpensive imaging devices described on pp. 448 and 492-3, and scanning hardware such as is used in **Immunicon's** "CellTracks"<sup>TM</sup><sup>2383,3006-9</sup> (p. 492) seem well matched to the intelligent microfluidic chip. I suspect that a book called *Practical Slow Cytometry* is waiting to be written.

### Cytometry Afield

#### The Lymphocytes of the Long Distance Runner

Haq et al<sup>2292</sup> reported reductions in CD3<sup>+</sup> cells following the running of a marathon; they felt the changes were attributable to increases in serum cortisol. Gore et al<sup>3685</sup> can detect illicit use of erythropoietin by runners and other athletes using a combination of flow cytometric erythrocyte measurements and biochemical assays.

#### War and Peace

Not far from Marathon itself, prisoners of war liberated from a camp in Bosnia were found by Dekaris et al<sup>2293</sup> to have increases in activated T cells, a decrease in CD4<sup>+</sup>/CD8<sup>+</sup> ratio, and lowered serum cortisol, along with general nutritional changes. The same group<sup>3641</sup> also reported increases in activated T, B, and NK cells in women displaced from their homes by war. Skarpa et al<sup>3642</sup> found increased numbers of

CD16+ and perforin-containing lymphocytes in patients with post-traumatic stress disorder, with the highest levels in those who had been tortured while in concentration camps.

Griffiths et al<sup>3643</sup>, at the U.K.'s Biological Defence establishment at Porton Down, examined the effects of combinations of vaccines and the nerve gas antagonist pyridostigmine bromide on the general health and cellular immune status of guinea pigs, attempting to determine whether the treatment might cause symptoms of what will undoubtedly soon be described as "Gulf War I Syndrome." Although animals did show immune responses to the vaccines, neither health nor immune function appeared to be adversely affected.

Biselli et al<sup>3644</sup> reported a stress-related decrease in the fraction of CD29+ CD8+ lymphocytes in military student pilots. Gruzelier et al<sup>3645</sup>, studying medical students at exam time, found that self-hypnosis mitigated the effects of stress on lymphocyte subpopulations, while Ruzyla-Smith et al<sup>3646</sup> reported that hypnosis only altered immune response significantly in highly hypnotizable subjects. I'm mesmerized.

### Blood, Sweat, and Tears?

In addition to blood, semen, and urine, fluorescence flow cytometers have been used to analyze cells from nasal secretions<sup>2292</sup>, saliva<sup>2293</sup>, cerebrospinal fluid<sup>2294</sup>, effusions<sup>2295</sup>, stool<sup>2296</sup>, and tears<sup>3022</sup>, by people who looked for and got relevant information from these specimens. No sweat yet, although there are papers on effects of exercise on the immune system<sup>3647</sup> and on DNA content of benign and malignant tumors of sweat glands<sup>3648</sup>.

### Pulp Nonfiction

A few years back, somebody sent me an e-mail expressing a great deal of enthusiasm for using flow cytometry to characterize particles in process waters from the paper industry. I can't find it. However, just a couple of weeks ago, I got another e-mail on the same topic from Lari Vähäsalo in Finland, who reached the same conclusion and, to judge from a recently published paper<sup>3649</sup>, an even greater level of enthusiasm.

### Flow Cytometry On the Rocks

Acritarchs are organic-walled microfossils widely distributed in sedimentary rocks. Although different types of acritarchs have been classified on the basis of morphology, it has been difficult to perform chemical and biochemical analysis on individual subpopulations. Moldowan and Talyzina and colleagues<sup>3674,5</sup> used a conventional droplet sorter, measuring forward and side scatter and fluorescence, to separate different classes of acritarchs for subsequent biochemical analysis and electron and fluorescence microscopy. Until recently, geologists and paleontologists may have thought "FACS" stood for "Fluorescent Acritarchs in Cambrian Sediments"; now they've got the real dirt on the subject, and may find more uses for the technology.

### To Boldly Go Where No Cytometer Has Gone Before

As I noted on p. 432, the flow cytometers from NPE Systems trace their ancestry to the RATCOM instrument that was supposed to have been used on the International Space Station<sup>2911-4</sup>. Changes in behavior of various leukocyte populations observed after space flight<sup>3650-54</sup>, and concern that conditions encountered in space could not be simulated adequately in an earthbound laboratory<sup>3655</sup>, provided the rationale for placing a cytometer in space; work on the design of such instruments and the necessary support systems has continued<sup>3656-9</sup>.

Partec has just announced that its new **CyFlow Space** instrument is to be used on the Space Station. I was involved in the original cytometer-in-space project, and suggested that a scanning laser cytometer might be more appropriate than a flow cytometer; I haven't changed my mind. I should have designed and built the machine, but I just wasn't enterprising enough.

Meanwhile, back on the home planet, the Defense Advanced Research Projects Agency (DARPA) decided that it would be possible to detect early effects of biowarfare agents by having soldiers in the field wear small flow cytometers, which would perform leukocyte counts at appropriate intervals, and funded **Honeywell** and **Micronics** to develop a microfluidic system for the purpose. This could give "present arms!" a whole new meaning.

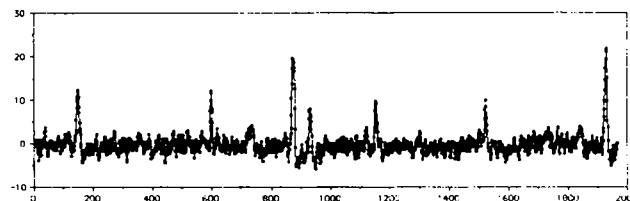

Figure 10-38. Flow cytometry *in vivo*. Courtesy of Charles Lin (Massachusetts General Hospital/Harvard Medical School).

From my point of view, however, the boldest new venture in flow cytometry is one that deals with inner, not outer, space. Figure 10-38 shows a trace of fluorescence pulses from leukocytes stained with a Cy5-labeled antiCD45 antibody and excited with a red laser. It looks pretty ordinary; the detector used was a conventional PMT, and cells were observed in a capillary. Well, not exactly a capillary, it was a venule in a mouse ear, and the mouse was alive, although not kicking very hard. Charles Lin and his coworkers at the Massachusetts General Hospital built the apparatus (for more information see <<http://www.massgeneral.org/wellman/faculty/lin/profile.asp>>), and we may all be able to learn something from it. *In vivo veritas*.

# 11. SOURCES OF SUPPLY

This chapter lists firms and organizations that sell or provide various services, supplies and items of equipment for which users and builders of cytometers have recurring needs. I have dealt personally with many of the listed companies; I haven't intentionally excluded anybody. The list that follows here picks up items in approximately the order in which they are discussed in the book. Addresses of U. S. branches, if any, are given for companies headquartered outside the U.S.

## 11.1 RESOURCES, SOCIETIES, JOURNALS

National Flow Cytometry Resource  
Bioscience Division, M-888  
Los Alamos National Laboratory  
Los Alamos, NM 87545  
Telephone (505) 667-1623  
Fax (505) 665-3024  
<http://lsdiv.lanl.gov/NFCR/>

International Society for Analytical Cytology (ISAC)  
60 Revere Drive, Suite 500  
Northbrook, IL 60062-1577  
Phone (847) 205-4722  
Fax (847) 480-9282  
[www.isac-net.org](http://www.isac-net.org)  
E-mail: [ISAC@isac-net.org](mailto:ISAC@isac-net.org)

*Cytometry* (incorporating *Bioimaging*)  
Editor-in-Chief: Charles L. Goolsby, Ph.D.  
Northwestern University Medical School  
Department of Pathology  
Ward Building 6-204  
303 East Chicago Avenue  
Chicago, IL 60611-3008  
Phone (312) 503-1847  
Fax (312) 503-1848

NCCLS  
940 West Valley Road, Suite 1400  
Wayne, PA 19087-1898  
Phone (610) 688-0100  
Fax (610) 688-0700  
<http://www.nccls.org>  
NCCLS used to stand for "National Committee for Clinical Laboratory Standards," but it is now a global organization that develops consensus documents for audiences beyond the clinical laboratory community.

## 11.2 OPTICAL SUPPLY HOUSES

The following supply tables, mounts, light sources, lenses, mirrors, filters, photometric apparatus, fiber optics, and other stuff besides. Their catalogs are educational as well as informative.

Coherent, Inc. (formerly Ealing Electro-Optics Inc.)  
5100 Patrick Henry Drive  
Santa Clara, CA 95054  
Phone (408) 764-4000  
Fax (408) 764-4800  
<http://www.coherentinc.com>  
A full line of optics; good buys on cylindrical lenses.

Edmund Industrial Optics  
101 E. Gloucester Pike  
Barrington, NJ 08007-1380  
Phone (800) 363-1992  
Fax (856) 573-6295  
<http://www.edmundoptics.com>  
A comprehensive line of optics and optical instruments.

Kinetic Systems, Inc.  
20 Arboretum Road  
Boston, MA 02131  
Phone (617) 522-8700 or (800) 992-2884  
Fax (617) 522-6323  
<http://www.kineticsystems.com>  
Optical tables and other vibration isolation equipment.

Linos (formerly Spindler & Hoyer)  
459 Fortune Blvd.  
Milford, MA 01757  
Phone (508) 478-6200  
Fax (508) 478-5980  
<http://www.linos.comportal/en/index.html>

Melles Griot  
16542 Millikan Avenue  
Irvine, California 92606  
Phone (949) 261-5600 or (800) 835-2626  
Fax (949) 261-7589  
<http://www.mellesgriot.com>  
I particularly like their (inexpensive!!) microscope objectives, mirrors, glass lenses, and beamsplitters.

Newport Corporation  
1791 Deere Ave.  
Irvine, CA 92606  
Phone (949) 863-3144 or (800) 222-6440  
Fax (949) 253-1680  
<http://www.newport.com>  
A complete line of optical tables, breadboards, and mounts.

OptoSigma  
2001 Deere Avenue  
Santa Ana, CA 92705  
Phone (949) 851-5881  
Fax (949) 851-5058  
<http://www.optosigma.com>

Rolyn Optics Company  
706 Arrowgrand Circle  
Covina, CA 91722  
Phone (626) 915-5707  
Fax (626) 915-1379  
<http://www.rolyn.com>

Siskiyou Design Instruments  
110 S.W. Booth Street  
Grants Pass, OR. 97526  
Phone (877) 313-6418  
Fax (541) 479-3314  
<http://www.sd-instruments.com>  
Optical platforms, micromanipulators, other hardware for life sciences applications and [confocal] microscopy

Technical Manufacturing Corporation  
15 Centennial Drive  
Peabody, MA 01960  
Phone (800) 542-9725 or (978) 532-6330  
Fax (978) 531-8682  
<http://www.techmfg.com>  
Optical tables, breadboards, and isolators.

Thermo Oriel  
150 Long Beach Blvd.  
Stratford, CT 06615  
Phone (203) 377-8282  
Fax (203) 378-2457  
<http://www.oriel.com>  
Oriel is a good source for arc lamp systems and power supplies, among other things.

Thorlabs, Inc.  
435 Route 206 North  
Newton, NJ 07860  
Phone (973) 579-7227  
Fax (973) 300-3600  
<http://www.thorlabs.com>  
Small breadboards and mounts, optics, diode detectors, and lasers. Will also do reasonably priced custom machining with a short turnaround time.

### II.3 PROBES AND REAGENTS

Linscott's Directory (<http://www.linscottsdirectory.com>), available in hard copy and online, can be useful for finding vendors of antibodies and other biological reagents.

Accurate Chemical and Scientific Corp.  
300 Shames Dr.  
Westbury, NY 11590  
Phone (516) 333-2221 or (800) 645-6264  
Fax (516) 997-4948  
<http://www.accuratechemical.com>  
Some monoclonal antibodies; good collection of photosensitizing dyes (cyanines, oxonols, etc.).

AdvanDx, Inc.  
222 Partridge Lane  
Concord, MA 01742  
Phone (781) 405-1654  
<http://www.advandx.com>  
PNA probes for microorganisms.

Aldrich Chemical Company, Inc.  
1001 West Saint Paul Ave.  
Milwaukee, WI 53233  
Phone (800) 325-3010 or (314) 771-5765  
<http://www.sigmaaldrich.com>  
Dyes and other chemicals.

Amersham Biosciences, Inc.  
800 Centennial Avenue  
P.O. Box 1327  
Piscataway, NJ 08855-1327  
Phone (732) 457-8000  
Fax (732) 457-0557  
<http://www.apbiotech.com>  
Biochemicals, CyDyes, and more.

Applied Biosystems  
850 Lincoln Centre Drive  
Foster City, CA 94404  
Phone (650) 638-5800 or (800) 327-3002  
Fax (650) 638-5884  
<http://www.appliedbiosystems.com>  
Custom PNA Probe Service.

Beckman Coulter  
11800 S.W. 147<sup>th</sup> Avenue  
Miami, FL 33196  
Phone (800) 526-3821  
Fax (800) 232-3828  
<http://www.beckmancoulter.com>  
Monoclonal antibodies, flow cytometry controls, beads,  
immunoassay products.

BD Biosciences/BD Immunocytometry Systems  
2350 Qume Dr.  
San Jose, CA 95131-1807  
Phone (877) 232-8995 (Ordering information)  
Phone (800) 223-8226  
Fax (408) 954-2347  
<http://www.bdbiosciences.com>  
Monoclonal antibodies, flow cytometry controls, beads,  
bead assays.

BioErgonomics, Inc.  
4280 Centerville Road  
St. Paul, MN 55127  
Phone (800) 350-6466  
Fax (888) 810-7189  
<http://www.bioe.com>  
Reagents for stem cell and T-cell isolation, cell stabilization  
and activation reagents.

Biomedica Corp.  
P. O. Box 8045  
Foster City, CA 94404  
Phone (800) 341-8787

Fax (510) 783-2299  
<http://www.biomedica.com>  
Biomedica are specialists in phycobiliprotein probes.

Biosource International  
542 Flynn Road  
Camarillo California USA 93012  
Phone (800) 242-0607  
<http://www.biosource.com>  
Antibodies, cytokines, peptides and custom products.

Boehringer Mannheim (see Roche Diagnostics Corporation)

Calbiochem-Novabiochem Corp.  
10394 Pacific Center Ct.  
San Diego, CA 92121  
Phone (800) 854-3417  
Fax (800) 776-0999  
<http://www.calbiochem.com>  
Antibodies, Biochemicals.

Caltag Laboratories  
1849 Bayshore Blvd. #200  
Burlingame, CA 94010  
Phone (650) 652-0468 or (800) 874-4007  
Fax (650) 652-9030  
<http://www.caltag.com>  
Monoclonal and polyclonal antibodies; avidin and strept-  
avidin conjugates utilizing tandem dyes, "fix and perm" kits.

Cell Signaling Technology, Inc.  
166B Cummings Center  
Beverly, MA 01915  
Phone (978) 921-6216 or (877) 616-CELL  
Fax (978) 922-7069  
<http://www.cellsignal.com>  
Antibodies to kinases and phosphoproteins.

CHEMICON International, Inc.  
28820 Single Oak Drive  
Temecula, CA 92590  
Phone (800) 437-7500 or (909) 676-8080  
Fax (800) 437-7502 or (909) 676-9209  
<http://www.chemicon.com>  
Monoclonal antibodies and custom services.

Chromaprobe, Inc.  
400 Brooktree Ranch Rd.  
Aptos, California 95003

KX-21, K-4500, SF-3000, SE-Series, XE-2100 hematology analyzers; UF-100 flow cytometric urine analyzer.

## 11.6 DATA ANALYSIS SOFTWARE/SYSTEMS

### Hardware and Software

Applied Cytometry Systems, Ltd.  
Unit 2 Brooklands Way  
Brooklands Park Industrial Estate  
Dinnington, Sheffield S25 2JZ  
South Yorkshire, England  
Phone 44 1909 566982  
<http://www.appliedcytometry.com>  
Applied Cytometry Systems, Inc. North America  
3453 Ramona Ave., Suite 10  
Sacramento, CA 95826  
Phone (800) 500-FLOW  
<http://www.appliedcytometry.biz>  
Developer of EXPO32 software for Beckman Coulter cytometers; WinFCM, a Windows-based data acquisition and control system for the BD FACS series; and StarStation, PC-based software for the Luminex 100 cytometer.

Beckman Coulter (see section 11.3 for address)

BD Biosciences (see section 11.3 for address)

DakoCytomation (see section 11.5 for address)

Partec GmbH (see section 11.5 for address)

### Commercial Software Sources

De Novo Software  
64 McClintock Crescent  
Thornhill, Ontario  
L4J 2T1 Canada  
Phone (905) 738-9442

Fax (905) 738-5126

<http://www.denovosoftware.com>

FCS Express and FCS Express Lite are data analysis and presentation programs running under Windows.

Ray Hicks

Phone +44 0797 4538647

Fax +44 0870 740 8595

E-mail: [Sales@FCSPress.com](mailto:Sales@FCSPress.com)

<http://www.fcspress.com>

FCSPress, a Macintosh program for FCM data analysis;

FCS Assistant, shareware utility for editing and exporting FCS data files.

Management Sciences Associates

6565 Penn Avenue

Pittsburgh, PA 15206-4490

Phone (412) 362-2000 or (800) MSA-INFO

Fax (412) 363-8878

E-mail: [info@msa.com](mailto:info@msa.com)

<http://www.msa.com>

MacLAS<sup>®</sup> and WinLAS<sup>®</sup> list mode data analysis software for Macintosh and Windows platforms, designed to integrate with clinical data management systems.

Phoenix Flow Systems (see section 11.3 for address)

MultiCycle AV (DNA analysis), Win-FCM (acquisition for FACScan), MultiTime (kinetic analysis), WinReport, QC Tracker (QC software), Apo-Soft<sup>™</sup> and MultiPlus (complete data analysis package) software for MS/DOS or MS Windows; Mac versions of some packages are available.

Tree Star, Inc.

20 Winding Way

San Carlos, CA 94070

Phone (800) 366-6045 or (650) 591-2854

Fax (650) 508-9186

<http://www.flowjo.com>

FloJo data analysis software for Macintoshes; a PC-compatible version should be available soon. ProJo, available free of charge, is a set of utilities that report, edit and administer FCS data files.

Verity Software House

P. O. Box 247

45A Augusta Road

Topsham, ME 04086

Phone (207) 729-6767

Fax (207) 729-5443

<http://www.vsh.com>

ModFit (DNA analysis), WinList (list mode data analysis), IsoContour, and ReticFit Software, running under Microsoft Windows. Macintosh versions of some programs are available.

### Noncommercial Software Sources

A comprehensive catalogue of free flow cytometry software is maintained by Steve Kelley at the Purdue University Cytometry Laboratories website:

<http://flowcyt.cyto.purdue.edu/flowcyt/software.htm>

AUTOKLUS is cluster analysis software available for PC's, Cytometry 14:649-659, 1993. Author: Tom Bakker Schur, Netherlands. Richard Allen Cox is enhancing AUTOKLUS. The original AUTOKLUS software is free from the Purdue cytometry laboratories website.

Cylchred, developed by Terry Hoy, is cell cycle analysis software based on algorithms by Watson *et. al.* (1987) Cytometry 8:1-8 and Ormerod *et. al.* (1987) Cytometry 8:637-641 with modifications by Ormerod (1991) and Hoy (1996-99). The package accepts histograms in FCS single parameter binary format with a maximum of 1024 channels. Cylchred has operated in a DOS environment since 1996 and has been transposed into C++ by Nigel Garrahan and compiled as a 32 bit product for Windows 95. By implication it will not operate under Windows 3.1.

[hoy@cardiff.ac.uk](mailto:hoy@cardiff.ac.uk)

<http://www.uwcm.ac.uk/study/medicine/haematology/cytonetuk/documents/software.htm>

CYTOWIN, developed by Daniel Vaulot with Jeff Dusenberry, is a windows 3.1 program designed to analyze single parameter histograms, two-parameter cytograms or list mode data. It can analyze data generated by the EPICS 5, Profile, Elite, FACScan, FACSort, and CICERO.  
<http://www.sb-roscoff.fr/Phyto/cyto.html#cytowin>

Flow Explorer 4.0 is "Postcardware" developed by Ron Hoebe (see the Web site). The program scans directories for [FCS] flow data list files and displays parameters, notes, histograms, and bivariate density, dot, and contour plots.

AMC, Celbiology CMO

R.A. Hoebe, Room 351.2

1105 AZ Amsterdam

The Netherlands

<http://wwwmc.bio.uva.nl/~hoebe/Welcome.html>

IDLYK is a software package that does neural net clustering, rudimentary cell cycle and multivariate analysis. It should run on any computer platform with the IDL graphics language (IDLYK is freeware, IDL is very much not). IDLYK was developed by:

Robert Habbersett

LS-1 MS888  
 Los Alamos National Lab  
 Los Alamos, NM 87545  
 E-mail: robb@beatrice.lanl.gov.

MFI is a program that calculates median fluorescence intensities from list mode data; it was developed by:  
 Eric Martz  
 Department of Microbiology  
 University of Massachusetts  
 Amherst, MA 01003  
 E-mail: emartz@microbio.umass.edu  
<http://www.umass.edu/microbio/mfi/>

RFlowCyt, is a basic R package for flow cytometry data analysis. R is 'GNU S' - A language and environment for statistical computing and graphics; it was developed by:  
 Tony Rossini  
 Research Assistant Professor of Biostatistics  
 University of Washington  
 rossini@u.washington.edu  
<http://software.biostat.washington.edu/wikis/front/RFlowCyt>

Soft Flow Hungary, Ltd.  
 Kedves u. 24  
 H-7628 Pecs, Hungary  
 Phone (36) 72 240064  
 Fax (36) 72 240065  
 Soft Flow, Inc. (North American office)  
 11513 Galtier Drive  
 Burnsville, MN 55337  
 Phone (800) 956-0100  
 Fax (612) 895-0900  
<http://www.visi.com-soft-flow/>

Soft Flow's FCAP-list is flow cytometry analysis software for Macintoshes. HPtoMac disk conversion software allows Macintoshes to read 3.5" Hewlett Packard diskettes. FCB Applications are flow cytometry BASIC programs. FCAP-list includes a code generator that automatically creates FCB program code of any manually performed data analysis process, where FCB is flow cytometry BASIC code. The products were originally sold commercially and are now available free of charge.

WinMDI is list mode data analysis and display software running under Microsoft Windows developed by Joseph Trotter when he was at the Salk Institute. It is available free of charge at <http://facs.scripps.edu/software.html>

## 11.7 CYTOMETER REHABILITATION/ADD-ONS

Alternative Biomedical Services, Inc.  
 2326 West 78th Street  
 Hialeah, FL 33016  
 Phone (877) 227-1687 or (305) 558-4996  
 Fax (305) 558-6511

<http://www.absbiomed.com>  
 Service, parts, reagents, reconditioned cytometers from Beckman Coulter and Abbott (CellDyn series).

 46560 Fremont Blvd., Unit 116  
 Fremont, CA 94538  
 Phone (510) 657-0102  
 Fax (510) 657-0151  
<http://www.cytetekdev.com>  
 Volumetric sample delivery systems; sample delivery module for fast kinetic studies; sample preparation unit.

Spectron Corporation  
 11025 118th Place NE  
 Kirkland, WA 98033  
 Phone (425) 827-9317 or (800) 747-8624  
 Fax (425) 827-6942  
<http://www.spectroncorp.com>  
 Reconditioned BD and Beckman Coulter cytometers

Laser upgrades (or downgrades to air-cooled systems) and the like are available from iCyt – Visionary Bioscience and Phoenix Flow Systems (see section 11.3 for address).

## 11.8 FLOW CYTOMETER PARTS

### Flow System Plumbing

Alloy Products Corp.  
 1045 Perkins Avenue, PO Box 529  
 Waukesha, WI 53187-0529  
 Phone (800) 236-6603  
 Fax (262) 542-5421  
<http://www.alloyproductscorp.com>  
 Alloy Products makes the stainless steel sheath tanks used by most flow cytometer manufacturers and by lab supply houses. Markups are lowest at the source.

Sigmund Cohn Corp.  
 121 South Columbus Ave.  
 Mt. Vernon, NY 10553  
 Phone (914) 664-5300  
 Fax (914) 664-5377  
<http://www.sigmundcohn.com>  
 Fine stainless steel wire, indispensable for removing 76  $\mu\text{m}$  particles from 75  $\mu\text{m}$  orifices.

Cook, Inc.  
P. O. Box 489  
Bloomington, IN 47402  
Phone (812) 339-2235 or (800) 457-4500  
Fax (800) 554-8335  
<http://www.cookgroup.com>  
Cook carries stopcocks and other medical plumbing.

Hellma Cells, Inc.  
80 Skyline Drive  
Plainview, NY 11803  
Phone (516) 939-0888  
Fax (516) 939-0555  
<http://www.hellmausa.com>  
Hellma makes cuvette-type custom flow chambers.

NSG Precision Cells, Inc.  
195G Central Ave.  
Farmingdale, NY 11735  
Phone (631) 249-7474  
Fax (631) 249-8575  
<http://www.nsgpci.com>  
NSG also makes cuvette-type custom flow chambers.

Research Developments  
3150-B Villa St.  
Los Alamos, NM 87544  
Phone (505) 662-4721  
Jim Coulter, formerly of Los Alamos National Laboratory,  
custom makes flow chambers and other parts.

Specialty Glass Products, Inc.  
2885 Terwood Rd.  
Willow Grove, PA 19090  
Phone (800) 850-4747  
Fax (215) 659-7217  
E-mail: [sales@sgpinc.com](mailto:sales@sgpinc.com)  
<http://www.sgpinc.com>  
Custom capillaries for stream-in-air systems.

Value Plastics, Inc.  
3325 Timberline Road  
Ft. Collins, CO 80525  
Phone (970) 223-8306 or (888) 404-5837  
Fax (970) 223-0953  
<http://www.valueplastics.com>  
Fittings and couplings to get from hypodermic components  
to the water mains; a good catalog.

Vita Needle Co.  
919-T Great Plain Avenue  
Needham, MA 02492  
Phone (781) 444-8629  
Fax (781) 444-3956  
<http://vitaneedle.com>  
Stainless hypodermic tubing cut to your specs, or mine.

## Photodetectors

Advanced Photonix, Inc.  
1240 Avenida Acaso  
Camarillo, CA 93012  
Phone (805) 987-0146  
Fax (805) 484-9935  
<http://www.advancedphotonix.com>  
Silicon photodiodes, avalanche photodiodes (APDs) and  
detector/preamplifier assemblies.

Burle Industries, Inc.  
1000 New Holland Ave.  
Lancaster, PA 17601-5688  
Phone (717) 295-6888 or (800) 366-2875  
Fax (717) 295-6096  
<http://www.burle.com>  
Photomultiplier tubes (PMTs) and accessories. Burle used to  
be RCA's PMT manufacturing operation.

Electron Tubes Inc.  
100 Forge Way, Unit 5  
Rockaway, NJ 07866  
Phone (201) 575-5586  
Fax (201) 586-9771  
<http://www.electron-tubes.co.uk>  
Previously part of Thorn EMI, Electron Tubes is the US  
affiliate of Electron Tubes Ltd in the UK and makes PMTs  
and accessories. I have used their PMT housings.

Hamamatsu Corp.  
360 Foothill Rd.  
Bridgewater, NJ 08807-0910  
Phone (800) 524-0504 or (908) 231-0960  
Fax (908) 231-1218  
<http://www.hamamatsu.com>  
Hamamatsu makes PMTs and accessories and pretty much  
has a lock on the flow cytometry market; they also supply  
photodiodes, APDs, and CCD camera chips.

PerkinElmer Optoelectronics (Headquarters)  
44370 Christy St.  
Fremont, CA 94538-3180  
Phone (510) 979-6500 or (800) 775-6786  
Fax (510) 687-1140  
<http://opto.perkinelmer.com/index.asp>  
E-mail: [opto@perkinelmer.com](mailto:opto@perkinelmer.com)  
PerkinElmer Optoelectronics  
2175 Mission College Blvd.  
Santa Clara, CA 95054  
Phone (408) 565-0850  
Fax (408) 565-0793  
Channel photomultipliers and photon counting modules  
PerkinElmer Optoelectronics  
22001 Dumberry Rd.  
Vaudreuil, Quebec J7V 8P7

Thorlabs (see section 11.2 for address)  
Diode lasers.

## II.10 OPTICAL FILTERS

### Color Glass Filters

All the color glass filter manufacturers sell through  
distributors, e.g., the optical supply houses listed in 11.2.

Corning Glass Works's color glasses are now made by:  
Kopp Glass, Inc.  
2108 Palmer Street  
Pittsburgh, PA 15218  
Phone (412) 271-0190  
Fax (412) 271-4103  
<http://www.koppglass.com>

Hoya Corp. USA  
101 Metro Drive, Suite 500,  
San Jose, CA 95110  
Phone (408) 441-3305  
Fax (408) 451-9562  
<http://www.hoya.co.jp>

Thermo Corion Optical Filters  
(formerly Ditric Optics, Inc.)  
8 East Forge Parkway  
Franklin, MA 02038-3148  
Phone (508) 528-4411 or (800) 598-6783  
Fax (508) 520-7583  
<http://www.corion.com>

Schott Glass Technologies, Inc.  
400 York Ave.  
Duryea, PA 18642  
Phone (570) 457-7485  
Fax (570) 457-6921  
<http://www.schottglasstech.com>

Newport Industrial Glass, Inc.  
10564 Fern Avenue  
Stanton, CA 90680  
Phone (714) 484-7500  
Fax (714) 484-7600  
<http://www.newportglass.com/homefil.htm>  
Distributor for all of the color glass filter manufacturers.

### Interference Filters

Chroma Technology Corp.  
74 Corron Mill Hill, Unit A-9  
Brattleboro VT 05301  
Phone (800) 824-7662  
Fax (802) 257-9400  
<http://www.chroma.com>

Thermo Corion Optical Filters (see address above)

Omega Optical, Inc.  
210 Main Street  
Brattleboro, VT 05301  
Phone (802) 254-2690 or (866) 488-1064  
Fax (802) 254-3937  
<http://www.omegafilters.com>

The optical houses of section 11.2 also make and sell interference filters. While Omega's and Chroma's stock filters may cost a bit more than some of their competitors', each Omega and Chroma filter comes with a transmission curve. Omega and Chroma will also make custom and semicustom (i.e., with additional coatings) filters.

### Neutral Density Filters

Many of the same companies that make interference filters also offer reflective neutral density (N.D.) filters. The color glass filter makers offer absorptive N.D. filters. Your local photo supply store probably has Kodak plastic neutral density filters, which may be all you need.

### Polarizing Filters and Optics

For cheap plastic polarizers, try your local photo shop; for fancier stuff, try the optical supply houses.

### Tunable Filters

Cambridge Research & Instrumentation, Inc.  
35-B Cabot Road

# 12. AFTERWORD

This is the space I reserved ahead of time in which to dot i's, cross t's, report late breaking news, and get in a few more opinions.

## 12.1 DOTTING I'S AND CROSSING T'S

As in the transitions between previous editions, I didn't renumber the old references. The Second Edition references started at 624, but reference 749 duplicated reference 523. The references in the Third Edition started at number 1027; those in this Fourth Edition are numbers 2315-3685. There are at least two duplicates; 3021 = 2682 and 3139 = 2616.

## 12.2 LATE BREAKING NEWS

### New Book

Well, not that new, but I seem to have missed *Cytometric analysis of cell phenotype and function*<sup>3660</sup>, edited by McCarthy and Macey, which appeared in late 2001.

### New Protein Stain

Ferrari et al<sup>3661</sup> have used a new stain, **Belgian red**, a metabolite of the fungus *Epicoccum nigrum*, to label cysts of *Giardia*. The material has excitation peaks near 400 nm and 525 nm; it is non-fluorescent until it interacts with proteins, producing a fluorescent complex emitting at 605 nm.

### Caveat on Fluorescent Caspase Inhibitors

Zbigniew Darzynkiewicz recently reported, in postings to the Purdue Cytometry Mailing List, that fluorescent caspase inhibitors (p. 380) may bind to other constituents of apoptotic cells, as well as to caspases. With Brian Lee and Gary Johnson, of Immunochemistry Technologies, he concludes that "While these reagents are good markers of apoptosis and very likely report activation of caspases or serine proteases, we currently suspect that mechanism of their retention in apoptotic cells may not be a strict function of their covalent interaction with caspase or protease enzymes." Further work on the additional binding sites should be published later in 2003.

### Polyamide Probes

Gygi et al<sup>3072</sup> used polyamide probes to discriminate chromosome 9 from other chromosomes with which it normally clusters (p. 479). The probes came from Peter Dervan and his coworkers at Caltech, who have investigated whether synthetic organic chemistry can improve on nature in terms of designing sequence-specific DNA binding polymers<sup>3662-4</sup>. Polyamides can bind to native double-stranded DNA, and, in some cases, can enter intact cells and modulate gene function<sup>3665</sup>.

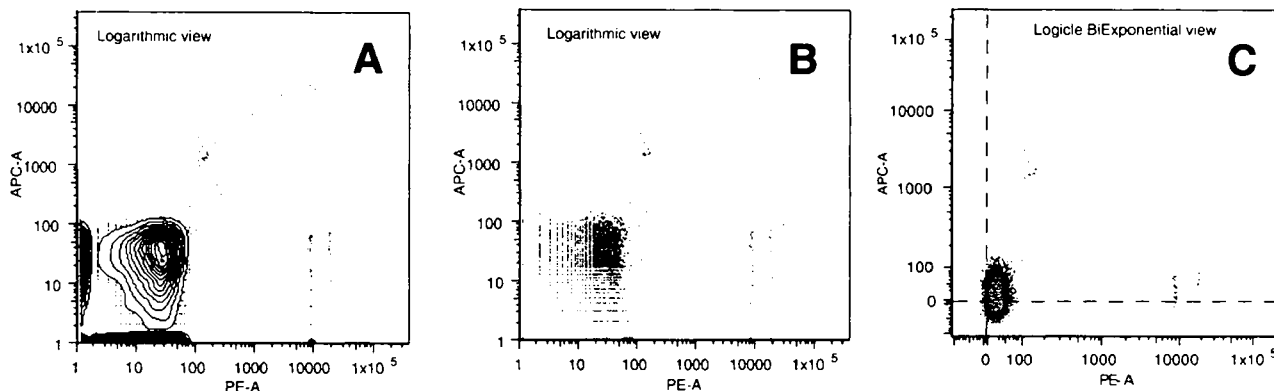

Figure 12-1. Tearing down the “picket fence” and reuniting the negatives using a BiExponential data transform instead of a logarithmic scale. Courtesy of David Parks and Wayne Moore (Herzenberg Lab, Stanford).

### Tearing Down the (Picket) Fences

My description of logarithmic amplifiers and fluorescence compensation as “Deals With the Devil” (p. 35) seems to resonate with many flow cytometer users, and it seems that the more colors they measure, the more frustrated they get about the whole business. High-resolution digitization lets us get rid of the logarithmic amplifiers, but the large dynamic range of immunofluorescence data demands that we keep the logarithmic scale, or at least something like it. When our high-resolution digitization is not quite as high-resolution as it should be, we get “picket fences” at the bottom of the scale (p. 207), whether or not compensation is applied to the data. But it gets worse.

After baseline restoration is applied, signals from particles with little detectable fluorescence, i.e., those that are “negatives” in a given fluorescence channel, produce signals with maximum amplitudes near zero volts (ground). However, there is always some noise on the baseline, which means that the value we capture might be slightly below ground rather than slightly above ground. Whether we use a log amp or do our conversions from linear to log scales digitally, we have a problem; as numbers approach zero, their logarithms approach negative infinity, and the logarithms of negative numbers are undefined. It is therefore common practice to apply a “fudge factor,” using additional circuitry at the input to a log amp or adding an appropriate constant if we are doing digital conversions, to keep the linear data values at least a little bit above ground.

Once we start compensating data, we are likely to end up with more negative values, and with a broader range of negative values, because the numbers we subtract from small signal values during compensation, whether we use analog compensation circuitry or digital compensation, are fixed fractions of large signal values, representing “ideal” compensation, while the small signal values, representing contributions from small numbers of photoelectrons, typically have a large variance. When we look at displays of compensated data on log scales, they almost invariably show one cluster of “negatives” plastered up against an axis, and another, discrete cluster just off the axis. Panels A and B of

Figure 12-1 provide a good illustration. The data in all three panels of the figure represent signals from blank particles (and a few from contaminating fluorescent particles); they were taken from a FACSDiVa digital pulse processing system, and processed by Dave Parks and Wayne Moore of the Herzenberg lab using a beta version of Tree Star’s FlowJo software incorporating a **BiExponential data transform**.

The log scale contour plot in Panel A shows three clusters of “negatives,” one along each axis and one occupying most of the first decade. The contour lines conceal much of the “picket fence” appearance of the data, which is much more obvious in the log scale color density plot in Panel B.

There isn’t anything sacred about the logarithmic scale; it just happens that it provides a convenient way of displaying data with a large dynamic range. Convenient, that is, as long as the data don’t include zero and negative values. When we were stuck with using log amps, we really didn’t have much choice as to what scale to use. Given the freedom made possible by high-resolution digital processing, Dave, Wayne, Mario Roederer et al decided to investigate other possible data transforms, looking for something that behaved like a log transform for large signal values, but was better behaved for small, zero, and negative values. What they came up with is a hyperbolic sine function that can have different coefficients in its positive and negative exponential components. Don’t worry about it; you won’t have to do the calculation. The bottom line is that the BiExponential function implemented in Wayne’s prototype “Logicle” program and in the FlowJo beta is close to linear at the low end and close to log at the high end, and, as can be seen from Panel C of Figure 12-1, it puts all the “negatives” into the single cluster in which our brains expect them to be found.

If there is a down side to all of this, it is that the function has a lot of coefficients, which may take some tweaking to get the data into the right shape. Most users don’t want to go there, and some who want to probably shouldn’t. So, the challenge for the programmers is to make the process automatic. Otherwise, I’ll stick with my counterproposal (p.

244) that we define the low end of the log scale as off limits for gating and just live with the artifactual multiple clusters. I have to admit, Panel C looks pretty nice.

### New Instrument: The BD FACSAarray™

BD Biosciences has recently introduced the FACSAarray, a benchtop analyzer designed for both multiplexed bead assays and cellular fluorescence measurements. It has 532 nm (green) YAG and red diode laser sources and a FACSCalibur-type flow cell, and takes samples from microtiter plates, measuring forward and side scatter and fluorescence at (I'm guessing) 575 and >660 nm (green-excited) and 660 and >700 nm (red-excited), using APDs and PMTs as detectors. The FACSAarray seems to be intended to go head to head with Guava and Luminex.

### Science Special Section: Biological Imaging

The 4 April 2003 issue of *Science* (Volume 300, pp. 1-196) contains a special section on biological imaging, introduced by Hurlley and Helmuth<sup>3676</sup>. Notable articles in the issue include a comparative review of light microscopy techniques for live cell imaging by Stephens and Allan<sup>3677</sup> and a report by Scorrano et al<sup>3678</sup> demonstrating the roles of BAX and BAK in regulating Ca<sup>2+</sup> transport from endoplasmic reticulum to mitochondria, a process without which apoptotic death cannot occur.

### Cytomics in Predictive Medicine: a *Clinical Cytometry* Special Issue and Other Recent Citings and Sightings

The May 2003 issue of *Clinical Cytometry* (*Cytometry*, Volume 53B, pp. 1-85) is a special issue on "Cytomics in Predictive Medicine," edited by Günter Valet and Atila Tárnok<sup>3679</sup>, including articles on the predictive utility of immuno-phenotyping in acute myeloid leukemia<sup>3680-1</sup> and chronic fatigue syndrome<sup>3682</sup>.

While those of us in the flow game may know and love *Clinical Cytometry*, I think we all have to admit that *The New England Journal of Medicine* has a considerably higher impact factor. Well, the May 1, 2003 issue of *NEJM* has an article<sup>3683</sup> and an editorial<sup>3684</sup> on the use of flow cytometric quantification of ZAP-70 kinase levels in chronic lymphocytic leukemia (CLL) cells to assess probable clinical course and outcome. The underlying biology is this: although the 50 to 70 percent of patients with hypermutated immunoglobulin heavy-chain variable regions usually have a good prognosis, those patients with unmutated genes do not. Using flow cytometry, Crespo et al<sup>3683</sup> found unmutated genes in all patients in whom at least 20% of B-CLL cells expressed ZAP-70 at levels equal to those found in T and NK cells; ZAP-70 expression itself was also determined to be of prognostic significance. Molecular methods that allow direct detection of the unmutated gene are "not [now] widely available in clinical practice<sup>3683</sup>," but Rai and Chiorazzi<sup>3684</sup> noted that ZAP-70 can be detected "by a relatively convenient and clinically available technology (multiparameter immunofluorescence flow cytometry)<sup>3684</sup>."

Back on pp. 468-9, I used Figure 10-9, from a 2002 paper by Perez and Nolan<sup>3000</sup> in which flow measurements of intracellular signaling kinases in T cell subsets were described, as an illustration of the current state of the art in

flow cytometry. A little more than a year after this paper appeared, we have a high-profile article establishing clinical relevance of flow cytometric kinase measurements in leukemic cells and a high-profile editorial pointing out the advantages of the technique. Perhaps not as dramatic as the progress from the recognition of SARS as a new disease to the identification and sequencing of the virus in three months, but still pretty impressive.

In April, 2003, Maryalice Stetler-Stevenson of NIH, Jerry Marti of FDA, and Bob Vogt of CDC rounded up a few of the usual suspects for a meeting on "Identifying the Optimal Methods for Clinical Quantitative Flow Cytometry." Renewed interest in this topic has followed from flow cytometric analyses done on patients undergoing treatment with monoclonal antibodies; data suggest that the number of antibody binding sites present on the target cell type(s) may be of relevance in determining response. If this turns out to be true at the most simple-minded level, it may be possible to improve the therapeutic index of monoclonal antibody therapy just by picking appropriate mixtures of antibodies, but that's getting way ahead of the game; what we need to do now is figure out how to get multiple laboratories to do reliable, reproducible quantitative measurements. Stay tuned.

### 12.3 ANALYTICAL BIOLOGY, SUCH AS IT ISN'T: IS THIS ANY WAY TO RUN A SCIENCE?

Flow cytometers are, unfortunately, too often used by, or under the direction of, scientists who neither know nor care to know the details of their operation. In the long run, that attitude cannot contribute to scientific progress.

Scientific instrument development follows a traditional pattern in which new principles in physics and chemistry are first applied by physicists and physical chemists, who domesticate them to the point at which they can be used by analytical chemists. The resulting technology then diffuses into the organic chemical, biochemical, and biomedical communities over a period of several years. Chemists and physicists are expected to build their own instruments if they can't buy the apparatus they need to answer the questions they are asking; biologists are not.

Thus, while there is an established discipline of analytical chemistry, there is not an established discipline of analytical biology. Moreover, biologists and medical researchers are generally not exposed to general principles of instrumentation and measurement during their training. They certainly don't learn how to build instruments. Clinicians may be knowledgeable about apparatus they use, but are generally unaware of instruments and methodology not already established in their fields of specialization.

While clinical medicine has been unflatteringly described as a cottage industry, the epithet applies to medical research as well. Researchers are encouraged to formulate complex hypotheses and ask intricate questions, but are typically given no guidance to speak of regarding the choice of methodology that must be used to test the hypotheses and answer the questions. Most senior researchers will opine that graduate course work in instrumentation, measurement, and methodology is unnecessary; the students will learn from books, from articles, from their advisers, etc.

Just where are all these books and articles? Who taught the advisers, and how much attention have the advisers paid to methodology since they were young investigators? The imagined teaching resources don't exist. People learn how to build and use instruments from hanging around other people who build and use instruments, and the rest of their colleagues don't understand their methodology, may not believe their results, and, worst of all, waste a lot of time and money doing experiments the hard way due to a lack of understanding of methodology.

There seems to be room for improvement in a lot of the methodology with which biomedical research propels itself along these days. At one time, I wanted to set up an academic department to train people to develop instruments and methods, but I'm probably too old now. If you want to learn, read (or re-read) the book, and find a mentor. If you're setting up such a department and would like to have an old dog help teach you and your students some new tricks, get in touch.

## 12.4 COLOPHON

A colophon typically goes at the end of a book and gives details on the typesetting and production. I'm putting mine here so I can finish with some other stuff.

The reviewers of the First Edition of *Practical Flow Cytometry* were uniformly negative about the typesetting, which was done with a Centronics dot-matrix printer and an Atari 800 computer (total system cost just over \$1,000). Many people assumed I was being chintzy about personal computer systems, and that I could have done much better using a \$3,000 (yes!) Apple II or a \$4,500 (yes! again) IBM PC for my word processing. Not true; when the book was typeset in late 1984, the setup I used and the Atari word processors provided the only means of getting a personal computer to produce the two-column, proportionally spaced text requested by the publisher. If I'd waited another two months, I could have produced nicer two-column proportional text using a letter-quality printer with the Atari. It took almost another year before the Apple and IBM word processors caught up.

Naturally, when the time came to consider putting out a Second Edition of the book, priorities one and two went to improving the typesetting and upgrading the sloppily scrawled and critically unacclaimed drawings that had illustrated the First Edition. By mid-1986, when I started evaluating the computer typesetting options, I was hearing all of these wonderful things about Desktop Publishing, and how it was already here for the Apple Macintosh and Coming Real Soon for the IBM PC. It sounded as if I could buy a single computer and a single software package to do everything I needed; set the type, draw illustrations, and do the layout, merging text and graphics. When I couldn't wait any longer for that ideal software, which was still not available for either the Mac or the PC when the second edition went to the printer, I had to wing it.

I first had to convert the files containing the text of the First Edition from single- to double-density Atari floppies, so I could read them on an IBM PC drive with the aid of shareware that translated them, more or less, into IBM format. The IBM format files were stripped of control codes

and edited, and new text generated, using the XyWrite III Plus word processor, which formatted and set the text in double columns, using 10 point Times Roman as the body type. Text pages were printed on an Apple LaserWriter Plus printer (over \$4,000!), which I lent to XyQuest for six weeks so they could fix the XyWrite printer drivers.

Merging of text and graphics was done by leaving space in the text page layouts for graphics and printing graphics separately. Graphics in IBM PC format were captured with SymSoft's HOTSHOT and printed on the LaserWriter Plus. Computer-generated drawings were done on a Macintosh SE using Cricket Draw and Apple's MacDraw, and also printed on the printer. Line art and photographs were copied on Canon copiers. The pages containing graphics were then inserted into the printer, and the text was printed in its proper location. This, believe it or not, was the most expeditious way to get the job done at the time.

Since I waited six years to do the Third Edition, I expected to be up to my armpits in fantastic page layout and document processing software when I started this one. Ha. I tried FrameMaker, PageMaker, and Ventura Publisher, on Mac and Windows platforms, and couldn't live with any of them. XyWrite had appeared in new DOS and Windows incarnations, which I didn't like either.

As luck would have it, Microsoft's version 6.0 of Word for Windows hit the stores just about the time I started typing. I had played around with version 2.0, which didn't hack it, but, luckily, I had translated all of the old files into Microsoft's Rich Text Format, so it was fairly painless to read them.

As we all think we know, cross-platform compatibility between Macintoshes and PC-compatibles is a piece of cake. Ha again. All of the drawings done on the Mac were done with old enough versions of the drawing programs so the new versions either wouldn't print them or would only convert them to PICT files much uglier than the originals. I ended up having John Brandes redo some of the old graphics using the Word for Windows drawing package; other old figures and photos and line art were scanned in by Chris Sychalski using a Hewlett-Packard ScanJet IIC, connected to an Apple Macintosh IIfx. Image files in TIFF (Tagged Image File Format) were transferred to the PC-compatibles via floppy disks and sneakernet.

A few drawings for the Third Edition were made with Corel Draw 4, Micrografx Windows Draw, and Chem-Window, a chemical structure drawing program. PC screen capture and image format translation were done with Pizazz Plus for Windows (Application Techniques, Pepperell, MA). My objective was to have the whole book, artwork and all, on the hard disk, so I wouldn't need to run paper through the printer twice, and I was very impressed that I could do the whole job with a word processor, rather than having to resort to a page layout program. So I went along with the rest of the world and switched all of my word processing to Word for Windows.

The Second Edition was printed on the Apple LaserWriter Plus, a 300 dpi PostScript printer. The Third Edition was printed on 600 dpi Hewlett-Packard LaserJet 4M and LaserJet 4MP printers, making it feasible to print halftones from photographs. These printers had PostScript

capability, but I used them in their native (PCL) mode, because, at least under Windows 3.1, they printed a lot faster that way.

By the time I started work on this Fourth Edition, I thought the layout part would be a piece of cake. In case you haven't heard, the typesetters used to print most books these days can work directly from Adobe Acrobat .pdf files, which are easy to generate from PostScript. I tried to use FrameMaker to do the book, but the available documentation was so atrocious that, after several months of screwing around, I still couldn't manage to get a single page of text to lay out properly, and decided to stick with Word. No picnic there, either. The computers at the lab and at the house and my laptop all had what was supposed to be the same version of Word for Office 2000 (separate copies of the program, of course; having written and sold software, I am against piracy). They also had the same printer drivers and the same fonts, but different computers would give me different layouts of the same text. Things improved when I moved from Windows Millennium Edition (hard to tell whether that is an operating system or just a resident virus) to Windows XP. It then turned out that the Acrobat Distiller printer driver would choke on my Word files and not produce .pdf files, and that each of the three PostScript drivers available for my 1200 DPI Lexmark Optra T610 printer was flaky in its own inimitable way. I settled on the least flaky one, which usually generated PostScript files that could be made into .pdfs.

After two major laptop hard drive crashes, I got smart and started keeping all of the files in duplicate on two external IEEE 1394 (FireWire) hard drives. And here I am. I need a new laptop; I was so desperate I even tried a titanium Mac for a while. Meanwhile, the folks at Wiley decided to play it safe and photograph my printed pages instead of trying to print the book from .pdf files. I hope what you see is what I got.

The body text for the Fourth Edition is 10 point Adobe Garamond; headings and captions are in Adobe Albertus MT. Many of the older figure labels are in Arial; the newer ones are in Helvetica. Shapiro's *Laws of Flow Cytometry* are set in Zapf Chancery. I'm still not sure whether symbols are coming out in Adobe's Symbol PostScript font or in Microsoft's Symbol TrueType font. There are a few other fonts scattered here and there. I hope you like the layout, but maybe I'll just send the publisher a double-spaced typed manuscript for my next book.

Since they were intended in part as revolutionary tracts, I thought it was appropriate that the First Edition and its predecessor should be Little Red Books. The Second Edition, with its redesigned cover, was, like Chinese pandas and newspapers, red all over as well as black and white. The blue cover design for the Third Edition was a little subdued, but Denise Papania has done a fantastic job with the cover for this one.

## 12.5 UNFINISHED BUSINESS

### AIDS and Infectious Disease in the Third World

As those of you who have been involved in cytometry for many years, or have read through this book, know, it was the

emergence of AIDS in the U. S. and Europe in the early 1980's that led to the widespread clinical use of fluorescence flow cytometry and the improvement of the previously shaky economic status of most of the instrument manufacturers. To borrow a phrase from the computer industry, HIV was, indeed, our "killer application." To their credit, many instrument manufacturers have attempted to produce smaller, more rugged, less expensive cytometric apparatus for clinical use in the Third World, but this has remained largely inaccessible to most of the African and Asian countries most affected by the epidemic.

I have described some approaches to affordable, practical cytometric systems for CD4+ T-cell counting on pp. 491-3. This subject is now a topic of discussion at the annual Cytometry Development Workshop, held every Fall at the Asilomar Conference Grounds in Pacific Grove, California, and attended by technical personnel from academic institutions, national laboratories, and industry. The Workshop has always had a strong ecumenical spirit, with information exchanged freely among competing laboratories and companies, and the session held in 2000 helped stimulate the development of the "EasyCount" instrument. More remains to be done; inexpensive cytometric apparatus originally developed for CD4+ cell counting could be adapted to meet the needs of other price-sensitive emerging markets in developed countries, e.g., food and water microbiology, and for other uses, e.g., clinical research on malaria and other parasitic diseases. The cytometry industry may need to have its arm twisted, as the pharmaceutical industry has had its arm twisted, to get the right products to resource-poor nations at the right price; if you have any leverage, use it. I'll be happy to help.

### A Center for Microbial Cytometry

The pace of development of instruments, reagents, and techniques optimized for cytometry of microorganisms, i.e., bacteria, nano- and picoplankton, fungi, viruses, and small unicellular eukaryotes – has been glacial.

For example: My colleagues and I published the first paper on flow cytometric detection of single virions in 1979<sup>94</sup>, and, although Harald Steen reproduced our results within a few years<sup>1246</sup>, the next published paper on detection of single virions appeared in 1999<sup>2336</sup>. As I pointed out on pp. 522-4, no current commercial instrument has sufficient sensitivity to make precise multiparameter measurements of substances present at levels below a few thousand molecules in individual microorganisms. We need an instrument optimized for that purpose; once we have it, it can be used to look at a lot of interesting small stuff, e.g., some strange bacteria<sup>3666</sup> and bacterial nucleic acids<sup>3667-8</sup> that seem to circulate in blood, circulating immune complexes<sup>825,1484,1820,3545</sup>, and platelet microparticles<sup>1460,3121-2,3132,3669-70</sup>, as well as at viruses and bacteria from various sources.

As I said on p. 516, bacteria are not just little eukaryotes. Many of the dyes with which we have become familiar as stains for eukaryotic cells behave differently in bacteria; some behave differently in different bacterial species. Relatively few monoclonal antibodies against microbial antigens are commercially available, and the choice of labels for those few that are labeled is limited. Other

specific reagents, e.g., rRNA probes, are also difficult to find. The immunologists and hematologists, even the most competitive ones, have cooperated over a generation to define the CD antigens, antibodies to which have become profitable for a number of companies; a similar cooperative effort will have to be undertaken to make better reagents available for microbiology.

It's not that there aren't a reasonable number of people who want and could benefit from improved instruments, reagents, and techniques for cytometry of microorganisms; the obstacle appears to be something like an activation energy barrier. In a word, the development process needs to be catalyzed; I am volunteering to be one of the enzymes. In 2002, I established a nonprofit corporation called **The Center for Microbial Cytometry**. The first mission of the center will be to get interested parties (from academia, government, and industry) together, by e-mail at first and by conference call or face-to-face meeting as appropriate later, to define (and catalog) the principal problems and currently available solutions. We can expect to find that, in many cases, one group of investigators has some solutions to another group's problems, which should lead to productive collaborations. Ideally, this would increase manufacturers' level of interest in providing the needed systems and materials, but, if it did not, we would at least have a data base and a clearing house that would facilitate do-it-yourself instrument modification and construction and exchange of reagents and techniques. The free market hasn't worked very well in this field over the past twenty or thirty years.

I don't expect the Center to accumulate a large staff and a building full of labs; we would only need people and resources on-site to do what none of our participating members was willing or able to do. I therefore also don't expect a large budget to be required, and it seems to me that the necessary funds could be obtained from some combination of government agencies, private foundations, and/or industrial donors. I'll start scrounging as soon as I finish writing. If you would like to be added to my list for further future mailings on the topic, e-mail me at <hms@shapirolab.com>.

### A Nobel Prize for Herzenberg and Kamentsky?

We all know that the developers of really useful scientific methods are at least as likely to get Nobel Prizes as those who discover new scientific facts and principles. If you've read this far in this book, I shouldn't have to convince you that cell sorting is a really useful scientific method. It would not have become one without the combined efforts of Mack Fulwyler, Len Herzenberg, and Lou Kamentsky.

Mack, then at Los Alamos, described cell sorting by droplet generation and electrostatic deflection in 1965<sup>67</sup>. Lou set the pace for the development of flow cytometry as an analytical cytologic tool during the 1960's, when he worked IBM's Watson Laboratory at Columbia University, and had added a sorter to his original instrument<sup>65</sup> by 1967<sup>66</sup>. Len recognized the potential of flow cytometry and sorting as a preparative method, and his lab at Stanford has been central in the development and refinement of the technology since the late 1960's, when the first fluorescence-activated sorter

was described<sup>68</sup>. Since that time, log amps, fluorescence compensation, reporter genes, new fluorochromes, and many other innovations have come out of the lab (reread this book!), which always seems to be measuring one more color than anybody else, and which also functions as a highly successful core lab, honing the cytometric skills of both experienced users and novices.

Mack is gone now, but there is still time for Len and Lou to win that trip to Stockholm. If you share my sentiments about this, and have clout with anyone eligible to nominate them for the Nobel Prize (see <<http://www.nobel.se/medicine/nomination/nominators.html>>), let that person know.

## 12.6 FLOW AND THE HUMAN CONDITION

The psychologist Mihaly Csikszentmihalyi wrote a book called *Flow: The Psychology of Optimal Experience* (Harper & Row, 1990). Of course, he wasn't talking about flow cytometry, but some flow experiences can be pretty optimal. Nobody has won a Nobel Prize for flow cytometry, but Len Herzenberg and Lou Kamentsky still might (they may not be old enough). Several people have made millions out of flow cytometry; Wallace Coulter made hundreds of millions. I know of marriages, and fistfights, in which flow cytometry played a role.

I haven't gotten rich doing flow, but I've been invited to a lot of interesting places, and met a lot of nice people. Since it's unlikely that anybody but the people I mentioned could win a Nobel Prize for cytometry or sorting itself, as opposed to winning one for using it intelligently, flow people tend to be more cooperative and less competitive than workers in some other fields. It is more obvious than ever that flow can't bring world peace, but it can occasionally bring individual people from places or groups with opposing philosophies together in a common cause, which is a start. I think I'll keep doing it.

### There's No Business Like Flow Business

There's no business like flow business  
When show business is slow.  
Where else can you play around with high-tech  
Lasers, and computers, and cell clones?  
I go in the lab each day and try tech-  
Niques out with my tech;  
It's in my bones.

There's no people like flow people;  
They smile where lights are low.  
Even when there's *Mycoplasma* in your cells,  
Your laser smokes and emits bad smells,  
Still, you wouldn't trade it for a stack of gels –  
Well, I wouldn't, I know.  
Let's go on with the flow!

## 12.7 ONE MORE THING

I almost forgot this, and it's very important: When your flow system clogs, whatever you do, don't smite it with your staff.
